For two reasons, the double-switch type of operation has become popular over the past 20 years. First, at intermediate follow-up, it seems that restoration of mLV to the systemic circulation with the mRV working under lower pulmonary pressures prevents the development of RV failure and significant tricuspid regurgitation. The mLV seems to be holding up well as the systemic ventricle. In the second situation, when RV dysfunction exists with associated tricuspid regurgitation, the recruitment of the mLV to the systemic circulation and the delegation of the mRV to the pulmonary circulation is appealing, as it reduces the work that the RV has to do, and the literature supports markedly diminished tricuspid valve regurgitation.³⁷ A double-switch operation is possible when the mLV pressures have been maintained at systemic levels (e.g., in a VSD pulmonary artery banded situation or when there is pulmonary atresia and VSD). However, when the mLV has been working as a pulmonary ventricle at low pulmonary artery pressures, it is not possible to perform a primary double-switch procedure expecting that the LV will support the systemic circulation. The LV needs some preparation to cope with the systemic workload. To create a ventricle strong enough to support the systemic circulation, many centers first place a pulmonary artery band to retrain the LV, and later perform an arterial switch. This circumstance arises with patients who have ccTGA without associated anomalies in whom over the first few years of life tricuspid regurgitation and a degree of RV failure has occurred in the setting of low pulmonary artery pressures. Then it is possible to retrain the LV and perform a double-switch procedure once the ventricle has been retrained. It can take 6 months to 1 year, or longer, to accomplish this.

Training of the Left Ventricle

Training of the LV has become an important aspect in congenital heart management since Mee's group,³⁸ and others showed that it was possible to retrain the LV in infants with dextrotransposition after a failing atrial repair to restore the LV to the systemic circulation. This concept has been applied to patients with ccTGA. The method used for training is similar in the two groups. A pulmonary artery band is placed around the main pulmonary artery acutely, to raise the mLV pressure to approximately 75% to 80% of the systemic pressure. Inotropic support may be necessary, and band adjustment to loosen or tighten the band may be needed over the first few days or weeks after the initial procedure. It may take 6 to 18 months for the mLV to be adequately trained so that systolic pressures are at systemic levels and ventricular

function is good, with an adequate thickness of the LV free wall. Training of the mLV is generally more successful in younger patients, and the upper age limit at which success can be expected is believed to be a maximum of 15 or 16 years.³⁹ Recently reported late outcomes of anatomic repair have highlighted concerns over the late performance of “retrained” mLVs.^{24,40} Although by no means a universal finding, some studies have suggested that banding even at ages older than 2 years may be associated with poorer late performance of the mLV (see below).⁴¹ In view of this, Vouhe and colleagues⁴² have suggested a novel approach of banding symptomless infants with isolated ccTGA as a means of sustaining mLV pressures and restoring septal geometry early in life. Although an attractive idea, this remains a controversial approach due to the unpredictable natural history in isolated ccTGA, some of whom require no intervention for many years, even indefinitely.

INVESTIGATIONS AND EVALUATION

Echocardiography, both transthoracic and transesophageal, allows a diagnosis of ccTGA to be made and can show the important intracardiac morphology. It can be repeated on many occasions, with minimal effect on the patient, to fine-tune the diagnosis. Cardiac catheterization is usually performed in these patients before surgical intervention and is useful in confirming the morphology of the ventricular septum, as there may be multiple VSDs, and in clearly showing the pulmonary artery tree when previous surgery has been performed to place a pulmonary artery band or to create systemic-to-pulmonary artery shunt. It also can show clearly the coronary artery anatomy if an anatomic repair is to be considered. When a mLV has been retrained with a pulmonary artery band, it is necessary to measure ventricular pressures. When there is concern about pulmonary hypertension, cardiac catheterization with manipulation of pulmonary vascular resistance in the catheterization laboratory is mandatory.

As for other forms of congenital heart disease, computed tomography scan and magnetic resonance imaging have been increasingly used to delineate anatomy, with magnetic resonance imaging being particularly helpful in demonstrating the relationship of the VSD to the aorta in assessing for suitability for Rastelli in the setting of unusual cardiac position. Three-dimensional echocardiography will undoubtedly also become more widely used as it becomes more available, particularly in assessing tricuspid valve regurgitation.

SURGICAL OPTIONS

Historically, the decision to correct ccTGA surgically was fairly straightforward: the associated cardiac anomalies would be repaired (physiologic repair), the VSD could be closed, the pulmonary stenosis would be relieved, and the tricuspid valve would be repaired or replaced with or without a pacemaker system. However, since the inception of the double-switch procedures, it is necessary to

decide whether to allow the mRV to remain in the systemic circulation or to use a double-switch procedure to restore by the mLV to the systemic circulation. This decision is made despite knowledge that historically the RV in the systemic circulation will deteriorate unpredictably, and even though long-term follow-up results of the double-switch procedure are still limited. The algorithm in [Figure 126-4](#) illustrates the possible surgical management for patients with ccTGA and their associated cardiac abnormalities. When longer-term results become available, indications may well change.

Physiologic Repair (Conventional or Classic)

In a physiologic repair, the associated cardiac defects are repaired so that the mRV remains as the systemic ventricle. The VSD is closed with a patch, pulmonary outflow tract obstruction is relieved directly by resection of obstructing tissues, and, when this cannot be performed adequately, a valved conduit from the mLV to the pulmonary artery is placed to relieve the obstruction ([Fig. 126-5](#)). If there is associated tricuspid valve regurgitation, the tricuspid valve can be repaired; this can be difficult, however, because of the difficult dysplastic abnormalities associated with this valve. Clefts can be closed and annuloplasty can be performed.

Cardiopulmonary Bypass in Physiologic Repair

Normal cardiopulmonary bypass with ascending aortic and bicaval cannulation is instituted. Core cooling is taken to 28° or 25° C (by nasopharyngeal measurement), depending on the surgical complexity. Initial dissection of the heart may be limited to the cannulation sites only, if this is a reoperation with further pericardial adhesions taken down on bypass. Having mobilized the heart fully (which can be difficult because of the position of the ventricles), the aorta is cross-clamped, and the repair is performed using standard cardiopulmonary bypass techniques.

Closure of the Ventricular Septal Defect

In congenitally corrected transposition, the VSD is commonly in a perimembranous position. In this situation, the conduction system passes superiorly around the pulmonary outflow tract. Accordingly, to avoid damaging the conduction system, continuous or interrupted sutures are placed through the RV margin of the VSD.²⁹ Access to the VSD is usually via the mitral valve or the pulmonary artery. If a ventriculotomy has to be performed, access to the VSD can be gained via the ventriculotomy.

Placement of the Valved Conduit

The valved conduit from the LV to the pulmonary artery (Hancock, Medtronic, Inc., Minneapolis, MN) usually passes to the right side of the aorta and is behind the sternum. Sometimes, the course of the conduit can be curved away from the sternal incision, but once the

FIGURE 126-4 ■ Algorithm for management of congenitally corrected transposition. Preferred management pathways are highlighted with yellow boxes and bolded arrows.

conduit is placed, it is wise to either close the pericardium or place a protective membrane behind the sternum to allow future reentry when the valved conduit needs replacing. A left ventriculotomy should be more toward the apex of the ventricle, taking care to avoid the papillary muscles of the mitral valve on the inner aspect of the ventricle and superior to the conduction system as it passes around the LV outflow tract.

Tricuspid Valve Repair or Replacement

Our experience with repair or replacement of the tricuspid valve in ccTGA is limited, because we electively try to perform a double-switch procedure when there is tricuspid valve regurgitation. Access to the tricuspid valve can be difficult if it is deeply seated in the RV. Reparative procedures are limited unless one finds a cleft in the valve that can be directly sutured, or a secondary orifice that can be closed. Various annuloplasties and reinforcing surgical rings can be placed in an attempt to gain competence in these difficult valves. In general, however, we do not believe this is advisable and would prefer to replace the valve if a secure repair cannot be made. In general, we replace the valve with a bileaflet mechanical valve,

with reinforced inverting mattress sutures. To preserve ventricular function, we preserve as much valve apparatus as possible when suturing the new valve.

Palliative Surgical Procedures

Various palliative surgical procedures may be applicable to patients with ccTGA. If there is cyanosis, a systemic-to-pulmonary artery shunt, usually a modified Blalock-Taussig shunt, is our preference. When there is pulmonary overflow resulting from a large VSD in infancy, a pulmonary artery band is placed, usually through a midline sternotomy. It may be necessary to place, in an epicardial position, either temporary or permanent pacemaker systems at the time of this palliative surgery.

Anatomic Repair

Cardiopulmonary Bypass and General Considerations in Anatomic Repair

Routine cardiopulmonary bypass techniques are used with cold crystalloid cardioplegia and topical irrigation of the heart with iced slush solution. The

FIGURE 126-5 ■ Physiologic repair of congenitally corrected transposition of the great arteries with pulmonary stenosis and ventricular septal defects (VSDs). The procedure includes VSD closure and placement of a valved conduit from the left ventricle (LV) to the pulmonary artery (PA). Ao, Aorta; LA, left atrium; MV, mitral valve; RA, right atrium; RV, right ventricle; TV, tricuspid valve.

heart is completely mobilized by dividing all the previous adhesions. Cardiopulmonary bypass is begun routinely by cooling to 22° or 18° C (by nasopharyngeal measurement) if circulatory arrest is anticipated. Often, a considerable amount of open-heart return is present, and short periods of low flow or even circulatory arrest are necessary to provide a clear field for the reconstructive surgery, particularly for the Senning procedure. Certain aspects of the bypass and cannulation, however, are peculiar to the anatomic repair. The superior vena cava is cannulated high underneath the innominate vein to allow room at the superior vena caval–right atrial junction for placement of the superior pulmonary venous Senning suture line. The inferior vena cava is cannulated low to place the cannula below the site of the Eustachian valve. The Eustachian valve can then be incorporated into the suture line of the systemic venous pathway. Having cross-clamped the aorta and arrested the heart with St. Thomas's cardioplegia solution, the atrium is opened.

Our practice is to use aprotinin infusion during the operation and tissue fibrin glue to help with hemostasis. Because these are long operations, we invariably do not close the sternum at the end of the operation. In addition, when a valved conduit passes directly behind the sternum in front of the heart, we delay sternal closure until myocardial function has recovered, so that the heart is not compressed by the valved conduit.

Surgical Anatomic Repair of Congenitally Corrected Transposition of the Great Arteries

In an anatomic repair (as opposed to the conventional repair, when the mRV remains as the systemic ventricle),

the mLV is restored to the systemic circulation. This is done by recruiting the systemic veins to the RV and the pulmonary veins to the LV by the Senning or Mustard procedure. Our experience is with the Senning operation, but the Mustard procedure can also be used. An arterial switch is then performed when the pulmonary outflow tract is unobstructed, and the pulmonary valve can become the new aortic valve. If there is pulmonary stenosis or atresia with a suitably large subaortic VSD, the LV can be rerouted to the aorta by baffling the VSD to the aortic valve as a Rastelli procedure. A valved conduit then connects the mRV to the pulmonary artery. The conduit can pass either side of the aorta, but if possible we route it to the left side to avoid the conduit sitting immediately behind the sternum.

Atrial-Arterial Switch (Double Switch). After cardiopulmonary bypass is commenced, the interatrial groove is developed, the aorta is cross-clamped, and cardioplegia is instituted. Cardioplegia solution is refreshed every 25 to 30 minutes, either via the aortic root or directly into the coronary ostia. The Senning baffles are formed.^{18,43} The right atrium is opened just anterior to the crista terminalis; this incision is extended inferior, anterior, and parallel to the crista to reach the Eustachian valve. The interatrial septum is opened adjacent to the mitral valve annulus, extending the incision superiorly and inferiorly. The superior incision is then extended deeply into the limbus, back to the root of the superior vena cava, and it usually exits through the previously delineated interatrial groove. The atrial septum is then separated from the right pulmonary veins hinging on the wall of the right atrium, to create the posterior wall of the systemic venous chamber. The interatrial septum is checked for perforations, which might need additional sutures. When there is a VSD, it is closed through the mitral valve, passing sutures from the rightward side of the ventricle as in the conventional repair. However, excessive traction on the crux of the heart (as occurs particularly with mesocardia or dextrocardia) can create temporary or permanent heart block, even if the sutures are placed carefully on the rightward side of the ventricular septum. We usually use a bovine pericardial patch or a Gore-Tex patch held in position with multiple interrupted Teflon pledgeted or native pericardial pledgeted mattress sutures. The smooth patch is used so that if there is neo-aortic valve regurgitation, the likelihood of hemolysis is reduced.

We then turn our attention to the arterial switch. The aorta is transected 1 to 1.5 cm above the entrance of the coronary arteries. If these are not clearly visible because of adhesions, the anterior wall of the aorta is opened carefully for about one third of its circumference, and the coronary arteries are visualized before aortic transection is completed. After pulmonary banding, there may be marked fibrosis between the aorta and the pulmonary artery.

Careful dissection continues, incising the pulmonary artery at the site of the band. Next, dissection proceeds backward and forward between the aorta and the pulmonary artery to mobilize these vessels. The coronary arteries are then cut out of the aortic wall with large cuffs to provide good buttons of tissue around the coronary ostia.

It may be necessary to release some of the commissures of the aortic valve to provide plenty of room around the ostia. The ostia must be protected by a large amount of aortic wall around them. The coronary arteries are then mobilized carefully to avoid damaging the coronary arteries. In particular, the left anterior descending coronary artery may pass close anteriorly to the aortic wall. Having dissected out the coronary arteries and mobilized the pulmonary arteries, the ductus ligament is ligated and divided. The pulmonary artery is transected and completely mobilized. Next, incisions are made into the sinuses facing the coronary aortic sinuses, so that medially hinged flaps are created.⁴⁴

The coronary arteries are then swung back into the facing sinuses of the pulmonary artery and anastomosed with 6-0 or 5-0 Prolene. If the pulmonary artery is enlarged, particularly when there has been a band placed distally, it may be necessary to reduce its size by resecting tissue from the noncoronary sinus. In patients with a dilated pulmonary root, we place a subcommissural circumferential suture (4-0 polydioxanone) to tailor in the new aortic root in an attempt to prevent neo-aortic valve dilation and regurgitation in this group of patients.²⁴ A patch of pulmonary homograft or autologous pericardium is then sutured into the aortic defects. When the great vessels are side by side, the pulmonary arteries are generally left behind the aorta. When they are more or less in an anterior-posterior position, the pulmonary arteries are moved anterior to the aorta. The aorta is then reconstructed with a 5-0 or 4-0 Prolene suture. At this point, the heart receives more cardioplegia solution, and we turn our attention back to the Senning procedure.⁴⁵

The posterior wall of the systemic venous chamber is reconstructed with a continuous 5-0 Prolene suture, starting at the posterior lip of the left atrial appendage and passing superiorly, leaving plenty of space superiorly between the posterior margin of the superior vena cava and the suture line. The posterior suture line is then continued inferiorly in a direct line back to the inferior vena cava. Where there is dilation of the left atrium, it is important to gather tissue aggressively from the left atrial wall onto the posterior edge of the systemic venous baffle. The anterior wall of the systemic venous chamber is then reconstructed, starting inferiorly with suturing at the Eustachian valve. If that is not present, the suitable position on the internal aspect of the inferior vena cava is used, extending onto the cut edge of the atrial septum. The coronary sinus can be laid open into the floor of the left atrium to create more volume to the inferior limb if required. Because of the displacement of the AV node in ccTGA, this inferior suture line can be taken to either side of the coronary sinus according to preference. We generally include the coronary sinus into the systemic venous atrium (which is contrary to the classical Senning in which the coronary sinus is left in the pulmonary venous atrium to avoid the AV node). The suture line is then continued superiorly on the cut edge of the intra-atrial septum between the mitral and tricuspid valves onto the extension of the crista terminalis around the atrial appendage and back, so that the systemic venous chamber is completed. On occasion, we have found it helpful to supplement the upper third of the systemic

venous reconstruction with a small patch of bovine pericardium or native pericardium to enlarge the superior vena cava opening.

It is noticeable in this group of patients that the tricuspid valve is set more deeply in the ccTGA, and that the angulation of the superior vena cava back into the tricuspid valve opening is more acute. When the atrial septum is intact and no dilation of the atrial chambers exists, the venous pathway may be small. Supplementation with the patch helps to open out the superior vena cava pathway. The pulmonary venous pathways are then reconstructed, with a direct anastomosis of the free edge of the right atrium to the cut edge of the right pulmonary veins, commonly using an augmentation patch of pulmonary homograft to provide additional volume. At this point, bypass rewarming is commenced, the heart is de-aired, and, with aortic root suction applied, the aortic cross-clamp is removed. If heart block is a problem, temporary pacing wires are placed. The pulmonary arteries are then reconstructed, anastomosing the pulmonary artery to the distal left and right pulmonary arteries. When the patient is rewarmed, cardiac bypass is discontinued in a routine manner. Temporary pacing wires are placed, and if there was heart block preoperatively, permanent epicardial pacemaker wires may be placed. A left atrial line is routinely placed through the old right atrial appendage. The chest is usually left open for the first 24 to 48 hours (Fig. 126-6).

Rastelli-Senning Procedure. The Senning procedure is similar to the double-switch procedure. Having created the atrial incisions, an incision is made in the mRV between coronary arteries and well away from the aorta. Through the ventriculotomy, the VSD is visualized and baffled over to the aorta with a Dacron or Gore-Tex patch sutured with interrupted mattress, Teflon-pledgeted sutures. Sometimes, a continuous suture is used superiorly around the infundibulum and aorta. Depending on surgical access, the valved conduit (usually a Hancock, Medtronic, Inc.) is sutured directly to the pulmonary arteries and proximally to the ventriculotomy, or the Senning procedure is completed and then the conduit is placed. The ventriculotomy suture line is reinforced with Teflon-pledgeted mattress sutures, inside-out in the heel of the graft, and outside in the toe. Usually, the graft is placed to the left side of the aorta, but any route that allows the graft to be away from the sternum is chosen (Fig. 126-7). Usually, at least part of the graft is behind the sternum, and a Gore-Tex membrane is placed between the pericardial edges to allow safer sternal opening at conduit change.⁴⁶

Recently, it has been possible to move the aorta back to the LV by aortic translocation, and to combine this with a Senning procedure and placement of a valve conduit from the mRV to the pulmonary arteries. This technique and its modification have been described by several authors and open further possibilities for anatomic repair when intracardiac baffling could lead to tunnel stenosis.^{23,47,48}

Senning or Mustard Procedure (Special Note). We use the Senning procedure; however, the Mustard

FIGURE 126-6 ■ Double-switch procedure. Ao, Aorta; LV, left ventricle; MV, mitral valve; PA, pulmonary artery; RV, right ventricle; TV, tricuspid valve; VSD, ventricular septal defect.

procedure can be used with equal validity. Sometimes, because of the position of the heart in the Senning procedure, the pulmonary venous chamber is enlarged with a patch of pulmonary homograft, or we use the Shumacker modification, with in situ native pericardium.⁴⁹

Postoperative Management

A degree of low cardiac output is not unusual after operations with these long and complex procedures. Median times were 149 minutes for cardiac bypass and 131 minutes for aortic cross-clamp.¹⁸ Inotrope and ventilatory support are maintained until the cardiac output improves, and ventricular function is monitored by sequential echocardiographic evaluation. At the end of the operations, cardiac function and the pathways into and out of the heart are checked by epicardial or transesophageal echocardiography.

After chest closure, the patient is gradually weaned from all support in the intensive care unit. Recently, one patient who survived required postoperative extracorporeal membrane oxygenation support for 4 days at our institution.

FIGURE 126-7 ■ Rastelli-Senning procedure for congenitally corrected transposition of the great arteries, with pulmonary atresia and ventricular septal defect. Ao, Aorta; LV, left ventricle; MV, mitral valve; PA, pulmonary artery; RV, right ventricle; TV, tricuspid valve.

Alternative Procedures

The one-and-a-half technique can be used as an alternative to complete anatomic repair. This incorporates a bidirectional Glenn procedure with the arterial switch or Rastelli component. This has the advantage of simplifying the atrial switch component because only the IVC pathway has to be rerouted to the tricuspid valve. This can be achieved by excising the atrial septum and using a single circular patch of Gore-Tex to commit the IVC flow to the tricuspid valve (the so-called hemi-Mustard procedure).^{50,51}

This technique is particularly attractive if there is concern over the size of the RV after a Rastelli procedure, or in patients in whom a previous Glenn has already been performed for palliation of pulmonary atresia. However, the Glenn may be problematic if pulmonary vascular resistance is slightly raised, and it will deny access for transvenous pacing (or ablation) should rhythm disturbances occur in the future. In addition, there are concerns that the functional performance of the one-and-a-half circulation might not be as good as complete biventricular repair.

An additional option in the setting of ccTGA with VSD and pulmonary stenosis is to perform a one-and-a-half repair keeping the mRV as the systemic ventricle. The VSD is closed, and the subpulmonary stenosis is partially resected.⁵² This is done so that RV pressures and mLV pressures are maintained at a higher level, approximately 50% systemic, to maintain alignment of the ventricular septum and possibly to prevent development of the tricuspid valve regurgitation and systemic RV dysfunction in the longer term. This may be particularly

applicable to situations in which a Rastelli-Senning repair is not possible because of the position of the VSD.

Finally a Fontan-type procedure may have to be considered if it is not possible by virtue of position of the heart, location of the VSD, and hypoplasia of a ventricle to perform a septation; however, this is uncommon.

RESULTS

Physiologic Repair

Results from many centers throughout the world are now available.^{9-11,19,30,32} Although the early mortality is low (5% to 10%), all groups have highlighted the long-term failure of the mRV associated with tricuspid regurgitation. The Toronto group³⁵ in particular highlighted this long-term problem, and the Mavroudis group,³³ in their article comparing physiologic and anatomic repair, stated the problem clearly. Thus, survival in these patients is 75% at 5 years and 50% at 20 years. In addition, 56% require reoperation in the 20 years of follow-up.

Anatomic Repair

Anatomic repair has grown in popularity because of the poor long-term outcome of physiologic repair. Early results for anatomic repair are available from centers in North America, Japan, and Europe and have reported encouraging results with early mortality in the region of 0% to 5%.^{*}

Longer-term follow-up is now becoming available. In our series of 113 patients, the early mortality was 4.4%, and actuarial survival in the double-switch group was 84% at both 5 and 10 years versus 92% and 77% in the Rastelli-Senning group (log-rank, $P = 0.98$).²⁴ Within this group of patients, we have identified a subgroup of high-risk patients in the neonatal or infant age-group with severe congestive cardiac failure requiring ventilation and inotropic support. All these patients were in the double-switch group. As expected, the early mortality was high in this group (3/17, 17%) but the corollary is that the early mortality in the remaining "elective" cases was lower (2%). Freedom from reoperation for all patients was 94% at 1 year, 85% at 5 years, and 76% at 9 years. There were no reoperations for tricuspid valve regurgitation; in fact, preoperative tricuspid regurgitation was universally improved. The reoperations, as expected, were for conduit change in the Rastelli group, and this will be a continuing necessity.

As longer follow-up results are reported, there is a concern over the incidence of late mLV dysfunction occurring in 15% to 20% of patients at 20 years postoperatively. This has been reported by both ourselves and the Boston and Stanford groups with similar findings.^{15,24,37,40} The etiology appears to be multifactorial and related to the development of aortic regurgitation, later age at repair (>10 years), and the need for preoperative mLV retraining with a pulmonary artery band. Aortic

regurgitation is specific to the double-switch group, in which the old pulmonary valve becomes the new aortic valve. All our patients had some mild degree of aortic valve insufficiency. In four patients, it was moderately severe, and it required aortic valve replacement in two patients. Similar results have been reported in other series.^{33,53}

A few centers performing the atrial-arterial switch procedure have commented that the mLV retrained by application of the pulmonary artery band may have more problems with LV dysfunction in the postoperative period. We have noted this also, as have others, but the relationship is by no means consistent.^{54,55} The Boston group have shown a greater risk of late mLV dysfunction in patients who were initially banded at older than 2 years, whereas there was no incidence of late dysfunction in patients banded at younger than 2 years.⁴¹ This group of retrained mLVs will certainly require careful follow-up. These findings add to the interest in the controversial approach of early prophylactic pulmonary artery banding in symptomless infants discussed earlier,⁴² which might protect the mLV in these patients from late failure.

It has also been noted that LV dysfunction is associated with a high incidence of patients requiring pacing and of patients who have a prolonged QRS interval.⁵⁶ Resynchronization with biventricular pacing has improved mLV function in these patients, with some individual cases of dramatic improvement.^{24,40} This may be of value in patients requiring pacemaker insertion after a double-switch procedure.

Despite these concerns, the outcomes of anatomic repair remain substantially better than both the natural history and for traditional physiologic repair, with more than 75% of patients sustaining good mLV function at 20 years. It is also important to note that the group of high-risk patients with severe cardiac failure have done particularly well, with no incidence of late mLV failure. Thus, with new operations, new problems arise. Only longer-term follow-up will show whether the good early results are maintained.

SUMMARY

The algorithm in [Figure 126-4](#) summarizes our current management for these patients. We believe that the LV in the systemic circulation will be of benefit for the majority of patients with this condition; therefore, our preferred management pathways are highlighted with red arrows. Longer-term studies will show whether the problems of new aortic regurgitation, LV dysfunction, and the need for conduit change will increase over time. The problem of RV dysfunction and tricuspid regurgitation has been solved, however. An anatomic repair should be suitable for the majority of patients. Development of heart failure in the older patient may still require tricuspid valve surgery or cardiac transplantation. At this time, it is not possible to retrain the LV in older patients.³⁹ Debanding and closure of the VSD is *not* our preferred option.

When only physiologic repair is possible because of the position of the VSD, or because of the age of an older

*References 12, 13, 15, 18, 24, 37, 40, and 53.

patient, we would agree with Mavroudis and colleagues⁵² that the mLV pressure should be maintained at approximately 50% of systemic pressures to maintain ventricular septal alignment. This can prevent development of tricuspid regurgitation and deterioration of RV function. When there is hypoplasia of one of the ventricles, or complex AV valve morphology with straddling, the only option may be to use Fontan palliation; however, this applies to a minority of patients.

Longer-term follow-up of this rare group of patients is now being reported. Although we believe that the initial enthusiasm for anatomic repair is justified, some centers have reported that there is no statistical difference in long-term survival rates between some patients undergoing physiologic repair and others undergoing anatomic repair.⁵⁷ Certainly, there is no real cure for ccTGA. There are surgical options, each of which has complications that will require management in the future. Continued surveillance is most definitely necessary.

Recurrent Left Atrioventricular Valve Regurgitation

This chapter treats only the congenital anomalies of the mitral valve to the exclusion of the mitral valve in atrioventricular (AV) discordance, the mitral valve in univentricular hearts, and the mitral valve of the hypoplastic left heart syndrome. It also excludes all acquired mitral valve disease, including the mitral valve insufficiency secondary to myocardial infarction or stunning as seen in anomalous origin of the left coronary artery from the pulmonary artery. Because repair of secondary or recurrent left AV valve regurgitation is often found in studies of the congenital mitral valve, it is included here. Although the division between congenital valve stenosis and congenital mitral valve insufficiency is classical and seemingly practical, we shall try to avoid it. Congenital valve stenosis and congenital mitral valve insufficiency generate different pathophysiologies and mechanisms of adaptation from the cardiovascular system, but they do have similar pathologies and associated lesions, they are often combined, and they require similar surgical techniques for treatment. Mitral valve anomalies associated with congenital connective tissue disorders, in which the

embryology of the mitral valve itself is normal, are also covered in this chapter.

EMBRYOLOGY OF THE MITRAL VALVE

The embryology of the mitral valve is complex. The understanding of the formation of the leaflets and suspension apparatus has evolved,¹ and the current approach is based on immunohistochemistry, in vivo labeling of cushion tissue, and scanning electron micrograph of human and chick embryos.² In humans, the mitral valve develops between the 5th and the 15th weeks of embryonic life. The leaflet and chordal tissue derive from the endocardial cushion tissue lying on the inner surface of the AV junction. The separation between atrial and ventricular myocardium is dependent on the sulcus tissue located on the epicardial side of the junction. As the cushion tissue elongates and grows toward the ventricular cavity, it becomes progressively delaminated from the underlying myocardium, and the leaflet transitions into a

funnel-like structure completely attached to the myocardium. Then, perforations into the valve leaflet appear. The perforations grow and form the chordae tendineae. The atrial aspect of the cushion generates the spongy atrial layer, and the ventricular layer generates the fibrous part of the mitral valve and the chords. The development of the papillary muscle takes place at the same time and is originated from the myocardium. A horseshoe-shaped ridge lies in the left ventricle. Progressively, the anterior and posterior parts of the ridge lose contact with the ventricular wall. They will form the papillary muscles, and as they increase in size, they stay in contact with the cushion tissue at the tip of the papillary muscle. The midportion of the muscular ridge will be incorporated into the apical trabeculations of the left ventricle.³

Several AV cushions participate to form the final mitral valve. The most important are the superior and inferior cushions. However, there is no symmetry in the role of these two cushions. The superior cushion tissue generates most of the anterior leaflet of the mitral valve, whereas the inferior cushion generates most of the septal leaflet of the tricuspid valve. Smaller cushions are involved in the formation of the mural leaflet of the mitral valve. The wedging of the aortic root into the superior bridging leaflet, which originated primarily from the superior cushion, separates the developing mitral valve from its septal attachments.

PATHOLOGIC FEATURES

Supravalvar Mitral Ring

Often considered a congenital anomaly of the mitral valve, the supravalvar mitral ring is a fibrous construction attached to the posterior annulus of the mitral valve; it runs from both commissures to the mid height of the anterior leaflet. The lesion is stenotic, often to a greater extent than might be suggested by the extension of the ring. This is more a result of the limitation of the opening of the anterior leaflet than of the actual diaphragm effect of the ring (Fig. 127-1). Strictly attached to the mitral valve annulus, it is to be differentiated from the cor triatriatum. Like the subaortic membrane in the left ventricular outflow tract, the supravalvar mitral ring is an acquired lesion resulting from turbulent flow through the

mitral orifice. The primary lesion of the mitral valve responsible for the turbulent flow can be obvious, stenotic, and regurgitant, or it can be discrete or mild and difficult to identify. It can be related to a prominent coronary sinus, as found in the left superior vena cava draining into the coronary sinus.^{4,5} It is perhaps for these reasons that the supravalvar mitral ring is prone to reoccur after surgical resection, unless the underlying anatomic anomaly has been identified and corrected.

Cleft Mitral Valve

The cleft mitral valve is often isolated and can be easily differentiated from a left AV valve in a partial AV septal defect.^{6,7} It is an actual cleft with no suspension apparatus on the edges of the defect. The cleft is centered on the aortic commissure between the noncoronary and left coronary cusps.⁶ Each half of the anterior leaflet at the midportion bears the attachment of the strut chordae. With time, the cleft mitral valve regurgitation will generate secondary lesions at the edges of the cleft, such as thickening, rolling up, and retraction. The defect is never stenotic and may generate only little regurgitation for a long time.

Lesions Associated with Lack of Valvar Tissue

Three major anatomic types of lesions are almost always associated with a lack of valvar tissue to various degrees and are worth characterizing: parachute mitral valve, papillary muscle to commissure fusion, and hammock or arcade valve. There is, however, a continuum between these three types and with the normal anatomy. The functional lesion can be either predominantly regurgitant or predominantly stenotic, or it can be both stenotic and regurgitant. In rare cases, the valve functions normally.

Parachute Mitral Valve

The parachute mitral valve can be found in isolation. It is, however, almost always associated with another cardiac anomaly, such as atrial septal defect (ASD), ventricular septal defect (VSD), or coarctation,⁸ and it is often integrated in Shone syndrome.^{9,10} It can also be seen in hypoplasia of the left ventricle, resulting in the need for univentricular palliation. The gross pathology shows a

FIGURE 127-1 ■ **A**, Two-dimensional echocardiogram of supravalvar mitral ring, apical view. The membrane attached at mid height of the anterior leaflet is characteristic. The posterior part of the membrane is only suggested by the hyperechogenicity of the posterior annulus. **B**, Intraoperative photograph of a supravalvar mitral ring. Note the implantation of the supravalvar mitral ring high close to the annulus on the posterior leaflet side (*inferior side of the picture*) and at the mid level of the anterior leaflet (*left side of the picture*).

FIGURE 127-2 ■ Macroscopic view of a parachute mitral valve. A large predominant papillary muscle distributes anomalous chords to both commissures. A small diminutive papillary muscle is seen to the right of the valve.

predominant single papillary muscle, with the orifice of the mitral valve overriding the tip of the papillary muscle. The spectrum of lesions for the suspension apparatus starts with complete fusion of the tip of the papillary muscle to the free edge of the valve.⁹ At the other end of the spectrum are chords that are relatively normal appearing, with good mobility of the leaflet (Fig. 127-2). The accessory papillary muscle is usually small and devoted to a short segment of the free edge, or even to the under-surface of the leaflet tissue, as would be seen if it were a larger-than-normal secondary chord. The leaflet tissue can be intact or perforated.

The functional class depends on the interaction between the amount of tissue and the mobility of the leaflet; presence and size of the fenestrations; and presence, length, and quality of the chords.¹⁰ The parachute mitral valve almost always has a stenotic component, because the gradient is fixed but the valve grows. These patients may not require a valve operation.¹¹

Double-orifice mitral valve, in which the lesser papillary muscle supports a complete orifice, is an exceedingly rare variation of the parachute mitral valve. It should be differentiated from the left AV valve, where an accessory orifice is often found when there is a diminutive or absent left lateral leaflet (mural leaflet).

Papillary Muscle to Commissure Fusion

Fusion of papillary muscle to the commissure,¹² also called short chordae syndrome, is defined by the presence of short chordae and a papillary muscle tip that is attached or fused to the commissural area of the free edge (Fig. 127-3). In the most extreme form, the chords are completely absent. The papillary muscles can be of normal

FIGURE 127-3 ■ Macroscopic view of a mitral valve with papillary muscle to commissure fusion. Extremely short chords are distributed to the anterior commissure (*left*). The posterior papillary muscle is almost fused to the posterior commissure (*right*).

size and volume. The valve is then generally more regurgitant than restrictive, which is because of the lack of valvar tissue and the restriction of the leaflet motion. When the papillary muscles are hypertrophied, the bulk of their mass is generally responsible for a predominantly restrictive valve.

Hammock or Arcade Valve

In patients with hammock or arcade valve, the suspension apparatus may have lost all resemblance to the normal anatomy. The papillary muscles are not identifiable, or there are multiple small papillary muscles behind the posterior leaflet. The leaflets are suspended directly by a network of chords directly attached to the posterior wall of the ventricle. This attachment is generally displaced toward the base of the heart, with excess tension on the anterior leaflet and extreme limitation of posterior leaflet motion. The valve is most often predominantly regurgitant.

Isolated Mitral Leaflet Hypoplasia

This rare condition is almost restricted to the middle scallop of the posterior leaflet.^{12,13}

Isolated Dilation of the Mitral Valve Annulus and Isolated Elongation of the Chords and Papillary Muscle

When the anatomy of the mitral valve is otherwise normal, it is difficult to ascertain the congenital origin of dilation of the mitral valve annulus and elongation of the

suspension apparatus, but they are included in most studies of congenital anomalies of the mitral valve¹⁴ and account for 15% to 40% of the patients in published studies of congenital mitral valve regurgitation.^{10,15,16} However, there is no evidence of their congenital origin. Elongation of papillary muscles can be found at birth in the mitral or the tricuspid apparatus, but the muscles usually have an ischemic, beige aspect. Sometimes, the ischemic origin is demonstrated by acute rupture at or shortly after birth. Isolated dilation of the annulus is not found at birth.

Both dilation of the annulus and elongation of the suspension apparatus are usually associated with significant volume loading of the left ventricle (e.g., with a large VSD or large patent ductus arteriosus). The pathophysiology is of initial dilation of the posterior annulus under the effect of the volume loading, followed by elongation of the marginal chords and prolapse of the free edge of the anterior leaflet. In rare cases, minor anomalies of the valvar tissue or the papillary muscles indicate a true congenital origin. When a patient older than 4 years has an isolated mitral regurgitation combining anterior leaflet prolapse and various degrees of posterior leaflet retraction, especially if the latter is thickened, a rheumatic origin should be ruled out when the patient originates from a geographical area of high prevalence.

Functional mitral regurgitations secondary to cardiomyopathies are not discussed here.

Accessory Mitral Valve Tissue

The interchordal spaces are filled with a dense network of valve tissue. When there is continuity between the anterior and the posterior leaflet, the accessory valvar tissue may generate a gradient directly related to the size of the perforations in the accessory tissue (Fig. 127-4).¹⁷ When the accessory valve tissue is entrapped in the left

ventricular outflow tract, the mitral valve may become regurgitant because of the traction exerted by the accessory valvar tissue on the anterior leaflet, which results in the valve's opening at mid systole¹⁸; however, in that case, the left ventricular outflow tract obstruction is the predominant hemodynamic lesion and is usually responsible for the diagnosis.¹⁹ Often, the accessory mitral valve tissue does not generate significant gradient or insufficiency.

Mitral Valve Disease with Excess of Leaflet Tissue, and Mitral Valve Prolapse

It is debatable whether the mitral valve prolapse syndrome—in its most common form, limited to the middle scallop of the posterior defect—is congenital. In a large population of neonates,²⁰ and using strict criteria, the incidence of mild bulging of the anterior leaflet was negligible and no prolapses were detected. This tends to prove that mitral valve prolapse is an acquired disease. In its common form, it is the exception when encountered in neonates and infants. In adults, the histologic anomalies are limited to the middle scallop of the posterior leaflet, with predominant elastic fiber alteration and myxomatous tissue proliferation.²¹

The more extensive form of mitral valve prolapse is, however, seen in neonates and infants. In this form, an excess of tissue is distributed to both the anterior and posterior leaflets, and histologic examination reveals extensive infiltration of the spongiosa with myxomatous tissue. The histologic anomalies are identical to those found in patients with Marfan syndrome,^{21,22} Ehlers-Danlos syndrome, and osteogenesis imperfecta. Marfan syndrome is an autosomal dominant disorder with varying penetrance. The mutation is found on the fibrillin gene. Ehlers-Danlos syndrome is represented by a

FIGURE 127-4 ■ Accessory mitral valve tissue. **A**, Long-axis view. The accessory mitral valve tissue is attached to the anterior and posterior leaflets of the mitral valve and blown like a windsock. **B**, Macroscopic view of the same tissue after surgical resection is characteristic of accessory mitral valve tissue attached to the suspension apparatus.

constellation of mutations linked to different subtypes.²³ The extensive form of the mitral valve prolapse syndrome is encountered in sporadic cases or in familial forms demonstrating autosomal dominant and X-linked inheritance. Three different loci, on chromosomes 16, 11, and 13, have been found to be linked to mitral valve prolapse, but no specific gene has been described.²⁴

Recurrent Left Atrioventricular Valve Regurgitation

After repair of complete or partial atrioventricular septal defect (AVSD), there are two main mechanisms for regurgitation in valves with a normally developed left lateral leaflet (LLL).²⁵ The cleft may be open because the cleft closure performed in the initial surgery has ruptured or because it was never done. In this case, the regurgitation occurs through the cleft directly. On color Doppler examination, the regurgitation jet is oriented vertically through the cleft.

Alternatively, when the cleft was completely closed and has remained so, the predominant mechanism for the regurgitation is the absence of a coaptation surface in front of the tip of the LLL. In the unrepaired AVSD, the small size of the zone of apposition is an inherent feature of these parts of the superior and inferior bridging leaflets. The direct closure of the cleft does not create a larger coaptation surface; in fact, the little coaptation surface that exists can be reduced and distorted by the cleft closure. This is even more so when the cleft closure has ruptured or is stretching the free edge of the valve. On color Doppler examination, the regurgitation jet oriented posteriorly hugging the posterior wall of the left atrium is characteristic of this mechanism (Fig. 127-5).

If the regurgitation is a long-standing condition, the secondary lesions or dysplastic lesions on the edges of the cleft are severe, with thickening and retraction of the leaflet tissue, and sometimes even calcification. On the other hand, the LLL is usually thin and pliable, with no secondary or dysplastic lesion. There is no restriction of the LLL motion and no prolapse.

In the presence of hypoplastic or absent LLL, the cleft cannot be closed at the time of the primary repair without generating inflow restriction. The residual or recurrent regurgitation occurs through the cleft. On an echocardiographic study, the anatomy is suspected when a strong asymmetry of the papillary muscles can be seen on the short-axis view of the left ventricle. The predominant papillary muscle, usually the anterior one, is connected to both superior and inferior bridging leaflets. The presence of a double orifice is also a strong indicator. It is usually directly suspended to a diminutive posterior papillary muscle and in the body of the inferior bridging leaflet. On Doppler examination, the regurgitation jet is oriented vertically through the cleft.

FUNCTIONAL CLASSIFICATION OF MITRAL VALVE ANOMALIES

Carpentier's functional classification of mitral valve anomalies describes leaflet motion, regardless of the

FIGURE 127-5 ■ Mechanism for the regurgitation in the absence of a zone of apposition facing the tip of the left lateral leaflet. The direction of the jet is posterior and hugging the posterior wall of the left atrium.

anatomy and the cause.²⁶ It is an essential tool for mitral valve repair and should be studied on echocardiography preoperatively.²⁷ It can also give significant clues to the lesions that will eventually be found during surgery.

Type I. Normal leaflet motion. The anomaly can be either a perforation or a defect of one or two leaflets, or an annular dilation. Annular dilation associated with a type II anomaly of the anterior leaflet is most likely functional.

Type II. Enhanced leaflet motion. Most pediatric mitral valve regurgitations with a predominant type II anomaly started as functional and progressively elongated the suspension apparatus of the anterior leaflet.

Type III. Restricted leaflet motion. The valve may be stenotic or regurgitant, or both. Most patients with congenital anomalies of the mitral valve belong to this type.

Table 127-1 shows the association between functional classification and the morphologic findings adapted from Carpentier and Brizard¹⁰ and Chauvaud and colleagues.²⁸

DIAGNOSIS

The diagnosis of a congenital mitral valve anomaly relies on the clinical findings, the chest radiograph, the electrocardiogram (ECG), and, most importantly, the echocardiographic study.²⁷ A positive diagnosis of an isolated mitral valve anomaly can often be made before the

TABLE 127-1 Functional Classification of Mitral Valve Anomalies

Functional Type	Anatomic Pathology	Surgical Technique
Type I	Posterior leaflet defect Cleft mitral valve	Posterior annulus plication Direct suture Patch enlargement
	Annular dilation	Adult-size annulus: remodeling annuloplasty with or without leaflet enlargement Less-than-adult-size annulus: posterior annuloplasty, leaflet enlargement
Type II	Elongated chords	PTFE chords, chordal shortening, chordal transfer
	Absent chords	Wedge resection, sliding plasty PTFE chords
	Elongated papillary muscle	Chordal transfer Sliding plasty
	Excess tissue	Papillary muscle shortening Chordal shortening
Type III	Lack of valvar tissue	Leaflet resection (techniques vary with patient age: triangular, quadrangular, central body of the leaflet) Posterior leaflet detachment and enlargement Anterior leaflet enlargement
	Papillary muscle to commissure fusion	Fenestration of papillary muscle Commissurotomy
	Parachute mitral valve	Fenestration of papillary muscle Splitting of papillary muscle Commissurotomy Posterior leaflet detachment and enlargement
	Hammock mitral valve	Mobilization of suspension apparatus, separation from posterior wall Anterior leaflet enlargement Posterior annuloplasty

PTFE, Polytetrafluoroethylene.

echocardiographic examination. However, when there are associated cardiac anomalies, the clinical investigation may only raise the index of suspicion of a mitral valve disease, or it may be missed completely. Echocardiography is part of the initial evaluation of all pediatric patients with cardiac signs, but when there are associated lesions, it is essential to the diagnosis of a congenital mitral valve anomaly. In most patients, the echocardiography shows the congenital nature of the anomaly by demonstrating the variance with the normal anatomy. The functional evaluation of the mitral valve and the impact of the lesion on the cardiovascular system are best made by echocardiographic study. Neither a catheter study nor a ventriculogram has any value in the diagnosis of or preoperative assessment for mitral valve disease, although the catheter study and angiography may be helpful for associated lesions (e.g., complex VSDs and some arch anomalies).

Clinical Examination

Patients rarely present with mitral stenosis during the neonatal period, but when they do, the associated lesions may predominate. Beyond the neonatal period, symptoms may include failure to thrive, dyspnea on exertion, pallor, hypotrophy, and a history of repeated chest infections. Signs of low cardiac output can be found, such as pallor and cold extremities, tachycardia, and dyspnea. Signs of pulmonary hypertension are present, with exacerbated second heart sound and palpation of the right ventricular impulse. A diminished first heart sound

suggests thick leaflets of limited excursion. A low-intensity mid-diastolic murmur is the only direct auscultation sign, and it can be absent in a low-output situation.

Patients presenting with mitral regurgitation in the neonatal period are rare. At all ages, patients with mitral regurgitation present with various degrees of failure to thrive and with dyspnea on feeding or exertion. An enlarged left ventricular impulse may be present, and a high-frequency, high-intensity holosystolic murmur is heard at the apex extending into the axillae.

Electrocardiography and Chest Radiography

The ECG shows left atrial and left ventricular enlargement in patients with mitral regurgitation. Right atrial and right ventricular enlargements are seen when pulmonary hypertension is present. In the pediatric population, there is almost always sinus rhythm.

Chest radiography demonstrates double density of the left atrial enlargement and various degrees of pulmonary plethora with an enlarged main pulmonary artery. Left ventricular enlargement in the presence of mitral valve regurgitation is evident.

Echocardiography

The echocardiographic study is essential. Systematically conducted, it provides all the information necessary for the diagnosis of the mitral anomaly, its severity, and its

impact on the physiology.²⁹ The anatomic lesion can usually be strongly suspected. Echocardiography provides indications for surgery and gives assistance to the surgeon in the repair.¹⁵

The four-chamber view obtained with the transthoracic echocardiographic study is best to provide an accurate transvalvar gradient and define the precise amplitude of any prolapse or restriction. The short-axis view of the mitral valve (en face view) gives a direct vision of the area of the mitral orifice and allows good localization of the origin of the regurgitant jet. It allows a precise analysis of the papillary muscles (presence, size, location, and symmetry). Transesophageal echocardiography is superior for anatomic details of the suspension apparatus and evaluation of the functional classification. The probe can be moved up and down in the esophagus, providing precise localization of the area of prolapse along the free edge of the anterior leaflet, using the anterior commissure (probe up) and the posterior commissure (probe down) as benchmarks.

For mitral stenosis, the peak instantaneous and mean gradients across the valve have to be interpreted according to the quality of the diastolic function of the heart and the associated lesions. The overall impact of the gradient on the indication for surgery has to be weighed with the pulmonary artery pressure, and even more with clinical tolerance.

Three-dimensional echocardiography is progressing rapidly with the exponential increase of computer power and miniaturization of the probes. However, the information generated is of little use in small patients because the spatial and temporal resolutions are still insufficient. Generally, in patients larger than 30 kg, the most obvious benefit of three-dimensional echocardiography is the ability to locate very precisely on the three-dimensional en face view image the site of a two-dimensional cut. It is then only on the two-dimensional cut that the degree of prolapse or restriction can be quantified precisely.

Other Investigation Techniques

Whatever imaging technique is used, there are limitations in small patients, in whom spatial and temporal resolutions are critical. Neither magnetic resonance imaging (MRI) nor computed tomography has enough spatial resolution for the valvar tissue or the suspension apparatus in small children.

MRI allows precise calculation of the ventricular volumes irrespective of the septal geometry; this may aid in making decisions about treating patients with small left ventricle in mitral valve stenosis.³¹ The regurgitation fraction is measured accurately. Gradients and flows are demonstrated with MRI. In small patients, MRI does not help with the analysis of the valve anatomy. On the other hand, MRI can provide useful functional and morphologic information preoperatively.³²

MEDICAL TREATMENT

Medical therapy should be vigorous when the annulus is too small to receive a mechanical prosthesis in the

anatomic position. When mitral regurgitation is predominant, the treatment should include an angiotensin-converting enzyme (ACE) inhibitor, diuretics, and, if necessary, red blood cell transfusion.³³ In patients with mitral stenosis, afterload reduction is contraindicated.

SURGICAL TREATMENT

Indications for surgical intervention in infants differ from those in adults, but the difference is related more to the size of the mitral valve annulus than to the age of the patient. When the annulus is close to an adult size, the timing of the surgical intervention is directly related to the probability of successful repair of the valve. One can now say that in patients older than 1 year of age, using a wide range of mitral valve repair techniques, repair of virtually all valves is an accessible goal. Valves with great probability of repair should be operated on as soon as the regurgitation is severe, regardless of symptom severity—especially valves that usually do not need annular stabilization. The timing is then related to the experience of the surgical team. Conversely, in patients with small annuli, an important multi-institutional retrospective study⁴ has demonstrated very strong risk association when there is a mismatch between the prosthetic size and the diameter of the recipient annulus.

In neonates and infants a repair can be technically challenging, and replacement is often possible only with mechanical prostheses in supra-annular position associated with significant mortality.³⁴ Therefore, surgery should be deferred as long as the patient can be managed medically. New techniques have been described recently to allow mitral valve replacement in annular position in small annuli, including in neonates.^{35,36} These techniques should allow for a slightly more acceptable rescue strategy and hence a more aggressive approach for severely symptomatic neonates or infants; they do not, however, represent a dramatic change in the treatment paradigm.

In pediatric patients, long-term ventricular function returns to normal in severely symptomatic patients when the operation is successful,^{37,38} which is different from the adult population and allows to wait longer for technical need. Recent retrospective series of mechanical valve replacements in patients younger than 24 months demonstrate favorable results. They describe patients who belong to the recent era with appropriate anticoagulation therapy and with prosthesis implanted in annular position.³⁹⁻⁴¹ An important multi-institutional retrospective study⁴² has demonstrated very strong risk association when there is a mismatch between the prosthetic size and the diameter of the recipient annulus (i.e., a ratio of prosthesis size to body weight of greater than 3).

On the other hand, repair of virtually all mitral valves for patients older than 1 year, using a wide range of techniques, is an accessible goal.^{15,28} In small mitral annuli, the repair is difficult, but replacement generates high mortality.^{34,43} The surgery should be delayed whenever possible, but it should be conducted without hesitation when it cannot be delayed,^{15,44} and associated cardiac lesions should be treated at the same time. For large

mitral annuli, repair is possible most of the time, and mitral valve replacement, when necessary, can now be done with very good long-term outcomes. Results of earlier series were less satisfactory.

Mitral Valve Replacement

Mitral valve replacement in the supra-annular position in infants should be avoided at all cost. This type of implantation is responsible for most or all of the perioperative and long-term deaths in units with experience of these patients.⁴⁵ Mitral valve repair in these cases is often a palliation, for the long or short term, but it allows annular growth and eventual replacement in patients who are in better condition technically.¹⁵

Mitral valve replacement in larger annuli is possible now, with excellent long-term results. Only mechanical valves should be implanted. Low-profile aortic valves have proved to be useful for pediatric mitral valve replacement. The valve must be removed from the valve holder and implanted with the opening toward the ventricular cavity. The bioprostheses have been associated with early degeneration and reoperation, and they should not be used in the pediatric age group.⁴⁶

Replacement of mechanical prostheses is not uncommon in pediatric units. The indication is usually the appearance of a gradient with pulmonary hypertension, at rest (on Doppler study or catheter study) or on exertion (on Doppler study).⁴⁷ A larger size can usually be implanted, and in exceptional cases, it may be more than two sizes greater than the prosthesis it replaces.⁴⁸ This is one of the most important motivations behind the policy of initial repair and postponement of the first replacement as much as possible. Technically, the replacement of a pediatric mechanical prosthesis differs significantly from replacement in the adult. Great care must be taken to remove all cuff tissue and pledgets. Everting mattress sutures, especially with pledgets, should be avoided, as they reduce the size of the annulus. Simple interrupted sutures or running polypropylene sutures are preferable. The mechanical valves implanted are designed for an adult flow at high velocity. When implanted in the mitral position in infants, they are submitted to approximately one fifth of the flow they are designed for and at low velocity. The target international normalized ratio (INR) has to be increased accordingly.

Two mitral valve replacement techniques^{35,36} in annular position have been recently described for neonates and infants. Both use the same glutaraldehyde bovine jugular valve available commercially either in a stented version (Melody, Medtronic, Minneapolis, MN) or an unstented version (Contegra, Medtronic) (Fig. 127-6).

Mitral Valve Repair

The techniques for mitral valve repair are described by Carpentier²⁶ for adult surgery, with modifications for pediatric patients and small congenital mitral valves.^{15,28} Cardiopulmonary bypass in Melbourne is conducted with moderate hypothermia 32° C, hemoglobin 10 g/dL, and a pump flow of 150 to 200 mL/min/kg or 1 liter/min/m². Warm-blood cardioplegia, administered every 20 to

FIGURE 127-6 ■ Implantation of a Contegra valve in annular position. Note that the commissure suspended with the artificial chordae is toward the ventricular cavity (as opposed to facing the posterior wall).

30 minutes, provides myocardial protection. Venous cannulation should allow as much room into the AV groove. The superior vena cava is cannulated directly, at a distance from the cavoatrial junction and the inferior vena cava immediately at the origin. Limited dissection of the groove is performed. After cross-clamping, the left atrium is entered via the AV groove. The exposure is enhanced with mattress sutures, inserted into the posterior annulus, that pull the valve upward and toward the operator. The snigger on the inferior vena cava pulls upward and to the left. A self-retaining retractor for mitral surgery must be adapted to the size of the patient.

Alternative approaches are less satisfactory. The transatrial septal approach does not provide an edge for the retractor blades to anchor and it exposes the conduction tissue to more pressure. It also takes time to reconstruct.

During the preparation for bypass, the mandatory preoperative transesophageal echocardiographic study is performed. Once the mitral valve is satisfactorily exposed, it is systematically analyzed, integrating preoperative information. The functional class is confirmed, whereas the extension of mitral valve prolapse or restriction is based on echocardiographic studies only. The location (A1 to 3, P1 to 3) is eventually confirmed intraoperatively. Then, the morphologic and anatomic examination is performed, which includes the following elements: a supra-valvar ring is confirmed or eliminated, and determinations are made of (1) the annular diameter; (2) the texture, aspect, and size of the mitral valve leaflets; (3) the number,

aspect, and distribution of the chords; (4) the presence of commissural tissue and dedicated suspension apparatus; and (5) the presence, size, location, and morphology of the papillary muscles. The examination finishes with a careful check for accessory mitral valve tissue in the interchordal spaces. The measured diameters of the annulus and of the mitral valve opening are compared with that calculated for the patient's body surface area. In Melbourne, we use a modification of the sizes provided by Kirklin and Barratt-Boyes.⁴⁹

The treatment is adapted to the predominant functional class. A correlation between functional class, anatomic pathology, and surgical treatment is shown in Table 127-1. The techniques included in the table are identical to those used in adult mitral valve repair surgery.²⁶ Few modifications are dictated by the size of the pediatric patients.¹⁵

Correction of Type I: Remodeling Annuloplasty

The annuloplasty is mandatory in all operations for mitral valve insufficiency, except in some patients with an isolated type I mitral valve anomaly without annular dilation, mostly cleft mitral valves. The purpose of the annuloplasty is to adapt the area of the mitral valve orifice (in systole) to the leaflet tissue available. Attempts to perform mitral valve repair without annuloplasty have resulted in recurrence.²⁸ A remodeling annuloplasty involves inserting a rigid adult-size ring (or a size larger than would be indicated by the area of the anterior leaflet). To achieve an adult-size ring in children or teenagers, the leaflet tissue must be enlarged—usually the posterior leaflet, less often the anterior leaflet, or both.^{50,51} In patients with a type III mitral valve anomaly, the detachment of the posterior leaflet to gain access to the suspension apparatus is used for the leaflet enlargement.¹⁵ When no device is available for the size of the patient, or when the device is thought to be too small, the annuloplasty is limited to the posterior annulus. The annuloplasty must incorporate both trigones. Experience with our own patients¹⁵ suggests that the greater stability of the annuloplasty is achieved with either a continuous strip of polytetrafluoroethylene (PTFE) or a row of compression mattress sutures tied over themselves (Fig. 127-7; also see Figs. 127-1, 127-2, and 127-3). We use a sheet of expanded PTFE folded two or three times, to avoid corrugating. Mattress sutures should not be tied too tightly.

Correction of Type II

Correction of type II mitral valve anomalies is rarely necessary in patients with congenital mitral regurgitation. Type II is mostly a secondary lesion, or it is seen with associated lesions (mostly large volume loading of the left ventricle), but correction is always required in patients with a connective tissue disorder and mitral valve prolapse. Multiple techniques are available to correct the enhanced leaflet motion.¹⁵ Whether techniques should be used in isolation or in combination depends on the extension in width of the prolapsus (i.e., localized or extended to the whole width of the free

FIGURE 127-7 ■ Posterior annuloplasty made with a band of two or three layers of an expanded polytetrafluoroethylene sheet. Best results are obtained when the posterior annuloplasty is kept continuous. Alternately, the annuloplasty can be achieved by tying the mattress sutures over themselves (compression sutures).

edge). It is the height of the prolapsus (based on the preoperative echocardiographic study) that will dictate the choice of the technique.

All techniques are efficient and reliable, providing that the correction restores a large surface of apposition between anterior and posterior leaflets. Overcorrection, however, generates stress directly on the repaired area and negates the stress relief provided by the surface apposition. All overcorrections eventually fail.

Artificial chords are used when chords of appropriate strength and quality are not available in the area of the prolapse. The insertion requires rigorous technique to avoid overcorrection and large knots at the free edge (Fig. 127-8). Artificial chords are safe for pediatric patients and allow adequate growth of the repair from the papillary muscle and the leaflet tissue.⁵²

Chordal shortening requires thin and flexible chords. The correction generates significant shortening of the chords and is performed only when high and localized prolapse is considered (Fig. 127-9).

Chordal transfer between secondary chords and the free edge is preferred to chordal transfer from posterior leaflet to anterior leaflet, because the length is naturally adapted for the correction of localized prolapse (Fig. 127-10). The chord should be detached from the body of the anterior leaflet with a minimal amount of valvar tissue. It is then attached to the free edge directly at the required length with a small running suture.

Wedge resection and sliding plasty generate different degrees of correction of prolapsus to multiple chords. They are well adapted to prolapsus extended to a large segment of the anterior leaflet free edge (Figs. 127-11 and 127-12).

Papillary muscle shortening is essentially used in Marfan and mitral valve prolapse for the correction of combined anterior and posterior type II (Fig. 127-13).

FIGURE 127-8 ■ Artificial chords of expanded polytetrafluoroethylene. Rigorous technique is necessary to avoid overcorrection and large knots at the free edge. 1, A template is made from a short plastic tube cut at the required length and slid over the distal part of the stitch. 2, This template can be taken from the facing posterior leaflet edge. 3, The free edge of the leaflet is lowered to the contact of the papillary muscle. The artificial chord is tied while the template is clamped. 4, The template is removed and the mattress suture is pulled to bring the knot in contact of the papillary muscle. AL, Anterior leaflet; PL, posterior leaflet.

FIGURE 127-10 ■ Chordal transfer. Only secondary chordae should be used and NOT the basal chordae.

FIGURE 127-9 ■ Chordal shortening. Note the extent of the shortening achieved.

FIGURE 127-11 ■ Wedge resection. Achieves limited shortening distributed to several chordae.

FIGURE 127-12 ■ Sliding plasty. Achieves controlled shortening for thickened chordae.

FIGURE 127-13 ■ Papillary muscle shortening.

Correction of Type III

Type III congenital mitral anomalies consist primarily of restricted leaflet motion and insufficient leaflet tissue, and their successful correction is essential, especially in the first year of life.

Mobilization of Papillary Muscles. Access to the suspension apparatus is necessary to adequately mobilize the papillary muscles. Access can be through the mitral valve orifice when it is sufficient, but often the mitral orifice is small and does not allow sufficient access to the suspension apparatus. In these situations, detachment of the posterior leaflet can provide good exposure to the papillary muscles. Adequate thinning, mobilization from the posterior wall, and splitting and fenestration of the papillary muscles can then be performed safely. The posterior leaflet is later reconstructed with enlargement of the leaflet tissue (Fig. 127-14).¹⁵

Enlargement of Valvar Leaflet with Pericardium Patch. Augmentation of the leaflet tissue is the only way to treat a lack of valvar tissue.¹⁵ The anterior leaflet, the posterior leaflet, or both can be extended. Extension of the posterior leaflet should be limited to less than half of the height of the leaflet; it can be limited to the area of the middle scallop. Alternatively, when the detachment is extended from one commissure to another, the extension should reproduce a shape with three scallops and two commissures to allow a large opening in diastole. Crescent-shaped patches with a short inner edge are stenotic and the stenosis worsens with time. The extension of the anterior leaflet should be done in the body of the leaflet, leaving a strip of valvar tissue close to the hinge point to avoid mechanical stress at this level. The height of the extension should not be greater than two fifths of the height of the leaflet, leaving the area close to the free edge intact to allow a supple and effective surface of coaptation. If possible, it should be symmetrical from trigone to trigone. Since the early 1980s, the best default material has been autologous pericardium treated intraoperatively with 0.625% glutaraldehyde. Long-term results have been somehow unpredictable. Animal studies have suggested that new treatment to bovine pericardium may provide a better alternative.⁵³ Long-term results in clinical valvar setting are not yet available.

FIGURE 127-14 ■ Detachment of the posterior leaflet. 1, Hammock or papillary commissure fusion. Access to the suspension apparatus is limited through the natural mitral orifice. 2, After detachment of the posterior leaflet, mobilization and splitting of the suspension apparatus can be performed easily, even in the smallest valves. 3, After repair. 4, With annuloplasty.

Resection of Supravalvar Rings and Accessory Mitral Valve Tissue. Resection of supravalvar tissue requires an excellent exposure of the leaflet tissue. The supravalvar tissue can sometimes be peeled off the valvar tissue. More often, careful blunt dissection is needed. If perforation of the anterior leaflet occurs, it should be closed with simple figure-eight sutures (Fig. 127-15).

Resection of accessory mitral valve tissue requires similarly rigorous surgical technique. A good exposure of the subvalvar apparatus is needed to perfectly delineate the mitral valve chords from what can be resected without compromising the integrity of the suspension apparatus (Fig. 127-16). Various approaches to the suspension apparatus may have to be combined, such as through the mitral valve orifice and the aortic valve, and via detachment of the posterior leaflet.

Repair of Recurrent Left Atrioventricular Valve Regurgitation. Two separate anatomies leading to different surgical techniques have to be identified according to the size of the LLL.²⁵ The most common one is the normally developed LLL. The least common is the absent or diminutive LLL.

In the presence of a normal LLL, in some cases, the AV valve can be repaired by suturing or resuturing the cleft. To achieve a stable long-term result with simple suturing, the cleft should be thin and pliable and there should be redundant leaflet tissue to avoid putting suture under stress and to allow for a large zone of apposition facing the tip of the LLL. When the cleft has not ruptured or when there is significant retraction of the edges of the cleft, the valve should be repaired with adjunction of valvar tissue and pericardial patch should be used. The

FIGURE 127-15 ■ Patch enlargement of the anterior leaflet to treat the lack of tissue in congenital valve or the retraction of the rheumatic leaflet.

FIGURE 127-16 ■ Excision of extravalvar tissue within a parachute mitral valve. Great care must be taken to preserve the suspension apparatus.

area of the combined superior and inferior bridging leaflet can be augmented at the septal end of the leaflets.³⁴ At Royal Children's Hospital in Melbourne, we prefer creating a coaptation surface in front of the LLL using the cleft patch augmentation technique.²⁵

The area of the cleft closure is débrided of all secondary lesions around the regurgitation zone. Sufficient resection is performed to reach pliable leaflet tissue. The area of the cleft is then closed with a long and narrow patch. The patch extends into the ventricular cavity so as to create a coaptation surface to face the tip of the LLL (Fig. 127-17).

In the case of absent or hypoplastic LLL, the cleft is reopened where it had been partially closed, and a surface of coaptation is constructed on both edges of the cleft. In this anatomy, at Royal Children's Hospital, three different techniques are used, according to the difficulty and

FIGURE 127-17 ■ Excision of supralvalvar mitral ring.

the anatomy; most commonly, the edges of the cleft can be directly suspended using expanded PTFE chords (Fig. 127-18). A patch may be necessary to increase the surface area of the superior bridging leaflet and favor the creation of a large coaptation surface between native valvar tissue. Alternatively, we have used a partial mitral valve homograft of adapted size to reproduce the zone of apposition. This technique has demonstrated very good immediate and intermediate results in our experience and should allow sufficient palliation time to wait until an adult-size prosthesis can be used.

The double orifice should not be closed, because it is never regurgitant and can produce a valuable area of valve opening.

RESULTS

Mitral Valve Stenosis and Predominant Stenotic Valves

Between 1996 and 2014, 42 patients, 21 of whom were younger than 1 year, were operated on for congenital mitral stenosis. The most common pathologies were supramitral mitral ring (as predominant mechanism) ($n = 15$), papillary muscle to commissure fusion ($n = 12$), and parachute mitral valve ($n = 6$). Fourteen patients had Shone syndrome. There were three deaths, all Shone syndrome patients and all eventually after secondary mitral valve replacement. There were 10 reoperations and 4 mitral valve replacements (2 mechanical and 2 Contegra).

Mitral Valve Insufficiency and Predominant Regurgitant Valves

Ninety-eight patients were operated on for predominant congenital mitral regurgitation. There were 33 patients with mitral cleft. All are alive; one needed a reoperation, and all but two have no or mild residual regurgitation.

FIGURE 127-18 ■ Re-do left atrioventricular valve repair. Most common anatomy with large left lateral leaflet and two papillary muscles. A narrow pericardial patch is sutured to the edges of the cleft and extended into the inflow of the valve to enlarge the zone of apposition facing the tip of the left lateral leaflet. Suspension to the free edge of the patch is done with artificial chords.

FIGURE 127-19 ■ Re-do left atrioventricular valve repair. Rare anatomy with absent left lateral leaflet. Suspension of the free edges of the superior and inferior bridging leaflet with artificial chords and posterior annuloplasty. Suitable when the edges of the cleft are flexible.

There were 65 patients with causes other than a mitral cleft, and in this group, 30 patients were younger than 1 year. This whole group had 13 reoperations and 5 deaths. The freedom from reoperation at 5 years for patients younger than 1 year of age compared with patients older than 1 year is significantly different: 59% versus 95.7% ($P = 0.007$). Two patients have had a mechanical replacement and one had a Contegra; all are alive.

Recurrent Left Atrioventricular Valve Regurgitation

Since 1978, more than 700 patients were operated on at Royal Children's Hospital in Melbourne for complete

or partial AVSD. From 1996 to 2008, 42 patients were reoperated on for recurrent severe mitral regurgitation with the technique described in this chapter.²⁵ Five patients had a diminutive or absent LLL, and 37 had a normally developed LLL. The 42 patients had one to four (2.36 ± 1.1) left AV valve repairs, not including valve replacement. The actuarial risk for needing a second reoperation in the normal LLL group was 41% (6% to 63%; 95% CI) in the direct cleft closure group as opposed to 8% (up to 82%) in the cleft patch augmentation group ($P = 0.04$). In the diminutive or absent LLL group (Fig. 127-19), three out of five patients eventually required valve replacement at 1, 10, and 12 years postoperatively.

Fetal Intervention

Hypoplastic left heart syndrome (HLHS) is characterized by a generalized underdevelopment of the left ventricle and its dependent structures: the mitral valve, the aortic valve, and the preductal and ductal aorta. Because the anatomic severity of HLHS constitutes a spectrum of disease, the value of a consistent, defined nomenclature has been recognized. Such a nomenclature has been proposed by the Congenital Heart Surgery Nomenclature and Database Project.¹ The project has proposed an operative definition for hypoplastic left heart syndrome as “a spectrum of cardiac malformations, characterized by a severe underdevelopment of the left heart–aorta complex, consisting of aortic and/or mitral atresia, stenosis, or hypoplasia with marked hypoplasia or absence of the left ventricle, and hypoplasia of the ascending aorta and the aortic arch.”

The treatment of HLHS has dramatically changed over the past 2 decades. With little to offer prior to Norwood’s introduction of stage I palliation in 1983,

treatment has developed into a three-stage progression to the Fontan operation. Although the 1-month mortality rate for untreated patients is 95%, the current 1-month survival rate among specialized centers approaches 80% to 90%.

This chapter discusses the anatomic and physiologic challenges posed by these patients, as well as the management schemes devised to meet them.

DEMOGRAPHICS AND INCIDENCE

Two large epidemiologic reports have estimated the prevalence of HLHS to be 0.16 to 0.18 out of 1000 live births.^{2,3} Males account for 57% to 67% of new cases, and the risk of sibling recurrence has been reported to be 0.5%.^{4,5} No environmental risk factors associated with the diagnosis of HLHS have been identified.⁶

CLINICAL PRESENTATION

On physical examination, children with HLHS may appear entirely normal at birth. Within hours to days, however, tachypnea and pallor may become apparent with nonspecific chest radiographic and electrocardiographic findings.^{7,8} Depending on the adequacy of the ductal and atrial communications, there may be rapid progress to acidosis, cyanosis, and cardiopulmonary collapse. An exception to this usual sequence occurs in neonates presenting with a restrictive atrial septum; these children will present immediately after birth in severe respiratory distress, respiratory acidosis, and cyanosis that is unresponsive to medical management.

Other congenital lesions should be sought. Natowicz and colleagues⁹ reported that 28% of patients with HLHS suffered from a genetic disorder, a major noncardiac abnormality, or both. Looking specifically at the central nervous system among infants with HLHS, Glauser and colleagues¹⁰ documented anomalies in 29% and microcephaly in 27%. Blood flow pattern in the fetus with HLHS may have important implications for brain development. Shillingford and coworkers¹¹ reported a correlation between microcephaly and the size of the ascending aorta. Dent and colleagues,¹² using magnetic resonance imaging (MRI) postnatally, identified ischemic lesions in 23% of patients. Thus, the preoperative evaluation of these neonates should also include genetic and neurologic evaluations.

DIAGNOSIS

Echocardiography has become the diagnostic procedure of choice in patients with HLHS. Details such as aortic valve size and status (atretic versus patent), aortic dimensions, origin of the coronary arteries, brachiocephalic branching, status of the atrial septum, function of the tricuspid and pulmonary valves, and presence of systemic or pulmonary venous anomalies should be sought. Coronary anomalies, although rare, are more likely encountered in the setting of mitral stenosis and aortic atresia and can take the form of coronary-ventricular fistulas, hypoplasia, tortuosity, or single coronary arteries (e.g., anomalous left coronary from the pulmonary artery).¹²⁻¹⁸ Coronary abnormalities may be more frequent in mitral stenosis–aortic atresia (MS/AA) variants of HLHS, and these patients undergo additional scrutiny (discussed in further detail, later).

Cardiac Catheterization

Cardiac catheterization in patients with HLHS should be reserved for those with equivocal anatomy who may be candidates for biventricular repair, for those in whom coronary anomalies are suspected, or to delineate abnormal pulmonary venous return.

Fetal Diagnosis

Improvements in fetal echocardiography have led to an increasing frequency of antenatal diagnoses of HLHS.

Tworetzky and colleagues¹⁹ reported that prenatal diagnosis was associated with improved preoperative clinical condition as well as improved survival after the Norwood operation. Unfortunately, improved survival following Norwood palliation in children with a prenatal diagnosis has not been consistently demonstrated.²⁰ Mahle and others²¹ have reported that although antenatal diagnosis improves these patients' preoperative clinical condition and may reduce the incidence of neurologic injury, an impact on surgical survival has not been shown.

PATHOPHYSIOLOGY

In HLHS, the right ventricle must support both the systemic and the pulmonary circulation. Pulmonary venous return must have access to the right atrium, via an atrial septal defect, via a patent foramen ovale, or, in rare cases, via anomalous pulmonary venous connections to the systemic veins. Systemic output, delivered via the ductus arteriosus, is entirely dependent on ductal patency (Fig. 128-1). Ductal involution may be a rapid process, restricting right ventricle–dependent systemic blood flow and leading to progressive metabolic acidosis, tachypnea, and irritability before cardiopulmonary collapse.

The functional size of the interatrial communication is an important physiologic determinant in these patients. In the presence of an unrestrictive atrial communication,

FIGURE 128-1 ■ Hemodynamics and oxygen saturations (*in circles*) of hypoplastic left heart syndrome in the unoperated state. Pulmonary venous return must cross the atrial septum (*arrow*), where there is mixing with systemic venous return in the right atrium. Systemic cardiac output is dependent on a patent ductus arteriosus. (Reprinted with permission from Jacobs ML: Hypoplastic left heart syndrome. In Kaiser LR, Kron IL, Spray TL, editors: *Mastery of cardiothoracic surgery*, Philadelphia, 1998, Lippincott-Raven, p 859.)

pulmonary blood flow quickly becomes excessive and the signs and symptoms of congestive heart failure predominate.

A subset of neonates are born with a mildly restrictive interatrial septum (gradient of 2 to 5 mm Hg), such that pulmonary resistance is modestly elevated. This often serves to balance systemic and pulmonary blood flow, and these children may be physiologically stable, requiring little intervention before surgery. Whenever possible, allowing spontaneous respirations in an awake child often allows for the neonate to regulate the balance of pulmonary to systemic blood flows, attaining a stable circulation that greatly simplifies their preoperative management.

Finally, a few children present with severe restriction of the atrial communication. These neonates suffer from a prompt and profound hypoxemia at birth, leading rapidly to a metabolic acidosis. This variant, the functional equivalent of obstructed total anomalous pulmonary venous return (TAPVR), represents a true hemodynamic emergency requiring immediate relief. As with obstructed TAPVR, medical management of patients with this variant is uniformly unsuccessful. Interventions designed to enlarge and maintain the atrial communication have been successfully applied, such as balloon atrial septostomy and stenting.²²

CAUSES

HLHS can be experimentally created in the chick embryo by left atrial ligation.²³ These experimental findings were anticipated clinically by Remmell-Dow and colleagues,²⁴ who suggested that abnormal development of the atrial septum, including underdevelopment of the eustachian valve and limbus, reduced right-to-left shunting at the atrial level, resulting in hypoplasia of the left heart structures. Premature closure of the foramen ovale has similarly been implicated, as have primary abnormalities of the aortic valve.²⁵⁻²⁷

Although identifiable genetic sequences have been reported to be associated with HLHS, their relevance remains unclear.²⁸ An understanding of the developmental factors leading to HLHS assumes new relevance as intervention during the process of cardiac morphogenesis itself (i.e., fetal surgery) is pursued.

SURGICAL TRIAGE

Patients satisfying all facets of the definition of HLHS are clearly destined for single-ventricle palliation. However, there are patients for which the decision between the pursuit of single-ventricle palliation and biventricular repair is not so clear. Once pursued, the ability to cross over to the competing treatment is difficult, and efforts to stratify patients with equivocal anatomy have been made. Rhodes and colleagues²⁹ combined four factors (body surface area, indexed aortic root dimension, left ventricle length, and indexed mitral valve area) to predict death after biventricular repair for critical aortic stenosis in the neonate. However, application of these

criteria to hypoplastic, but nonstenotic, left heart structures using Rhodes's criteria has proven unsatisfying, as these criteria appear to be too stringent in this setting.³⁰ Recognizing this, the Congenital Heart Surgeons Society (CHSS) sponsored a multi-institutional study to delineate the outcomes and risk factors of critical aortic stenosis in the neonate.³¹

Presented by Lofland and colleagues,³¹ this study identified multiple morphologic and functional factors that can be used to predict which surgical approach, single-ventricle palliation or biventricular repair, is more likely to result in the survival of any particular patient. This study determined that solution of a multivariable equation using these factors can predict a patient's survival. This equation, which can be found on the CHSS website (www.chssdc.org) is as follows:

$$\begin{aligned} \text{Survival benefit} = & \text{intercept} + (\text{age at entry}) \\ & + (\text{z-score of aortic valve at the sinuses}) \\ & + (\text{grade of EFE [endocardial fibroelastosis]}) \\ & + (\text{ascending aortic diameter}) \\ & + (\text{presence of moderate or severe tricuspid regurgitation}) \\ & + (\text{z-score of the left ventricular length}) \end{aligned}$$

The prediction model was tested and refined by Hickey and the CHSS.³² They reported that the consequences of inappropriate pursuit of a repair strategy (biventricular versus single ventricle), as predicted by the model, was minimal for single-ventricle palliation but was very significant among patients undergoing biventricular repair. This report underscores the importance of the initial decisions made when assessing and triaging neonates with borderline left heart structures to a treatment strategy.

MANAGEMENT

The natural history of HLHS is dismal: 95% of untreated patients die within 1 month.³³ Medical treatment modifies the natural history, primarily by delaying the demise.³⁴

The surgical management of HLHS represents the paradigm from which a generalized approach to the shunted single ventricle has evolved. Simply stated, the cardiovascular system in HLHS consists of a single pumping chamber supporting two parallel circulations. These parallel circulations can be considered to be in competition with each other for blood flow. For any given cardiac output, the flow apportioned to each circulation is inversely proportional to the resistance of that circulation (i.e., high pulmonary vascular resistance, low pulmonary blood flow). Thus, efforts to control the circulation have focused on controlling the competing vascular resistances. These efforts have generally involved manipulation of the pulmonary vascular resistance using inspired gasses (oxygen, carbon dioxide [CO₂], and nitrous oxide) and pressures.³⁵⁻³⁸

More recently, an alternative approach that targets manipulation of the systemic vascular resistance to maintain the balance between the pulmonary and systemic circulations has been shown to be effective.

Manipulation of the Pulmonary Vascular Resistance

Carbon Dioxide

Inspired CO₂ has been suggested to improve the hemodynamic status after the Norwood operation.³⁵ Tabbutt and colleagues³⁹ compared the use of hypoxia (17% fraction of inspired oxygen [FiO₂]) to CO₂ in 10 neonates with HLHS prior to the Norwood operation under the conditions of fixed minute ventilation, anesthesia, and paralysis. Although both strategies reduced the ratio of pulmonary to systemic blood flow (Qp/Qs), CO₂ increased both superior vena cava co-oximetry and cerebral oximetry, whereas hypoxia reduced these indices of oxygen delivery. Bradley and coworkers⁴⁰ reported similar results among postoperative patients. It is important to note, however, that these benefits were only realized when the *minute ventilation* remained constant.

Although thought by some physicians to reflect a direct effect, there is evidence showing that the increase in pulmonary vascular resistance is reversed by alkalization, suggesting that the effect is mediated by [H⁺] and pH.⁴¹

Oxygen

Because the neonatal pulmonary vasculature is also sensitive to the concentration of inspired oxygen, hypoxic mixtures incorporating nitrogen have also been used to control the circulation in patients with HLHS. Animal models have shown that nitrogen-induced hypoxic mixtures increase the pulmonary vascular resistance and increase systemic blood flow. However, the prolonged use of hypoxic mixtures has been shown to quickly induce anatomic changes in the pulmonary vasculature. In animals, changes in arterial wall thickness and muscularity can be seen within 24 hours, and fewer intra-acinar arteries are recruited into the circulation.⁴²⁻⁴⁴

Day and colleagues⁴⁵ reported their clinical experience using hypoxia to manipulate the pulmonary vascular resistance in 20 neonates with single-ventricle, duct-dependent circulation awaiting heart transplant. Of these 20 patients, 8 survived; of the 10 patients who underwent lung biopsy or autopsy, 9 showed medial hypertrophy in distal arterioles, and 7 of these 9 patients died. Although the outcome cannot be completely ascribed to hypoxic management, this strategy suggests that prolonged supportive care of the neonatal single ventricle may expose these patients to significant risks.

Systemic Vascular Resistance

Manipulation of the systemic vascular resistance is a demonstrated means of controlling the shunted circulation. In fact, our ability to pharmacologically control the systemic vascular resistance probably exceeds our current ability to selectively manage the pulmonary vascular resistance. This clinical approach usually uses an irreversible α -adrenergic antagonist, phenoxybenzamine, to achieve systemic vasodilation. The desired systemic vascular resistance, defined as that which optimizes the Qp/

Qs and systemic oxygen delivery, is then obtained by titrating an α -adrenergic agonist, usually norepinephrine. Specifics of this approach have been reported in the literature.⁴³⁻⁴⁵

A review of this strategy identified the use of phenoxybenzamine, continuous systemic venous oxygen monitoring, and the reduction of deep hypothermic circulatory arrest (DHCA) time as factors favoring survival to the bidirectional Glenn operation.⁴⁶ To date, no studies directly comparing outcomes for these two fundamentally different management schemes have been performed.

OPERATIVE PROCEDURE STAGE I

The anatomic goals of the stage I or Norwood operation for HLHS is threefold: (1) to provide unobstructed blood flow from the systemic right ventricle to the systemic circulation, (2) to ensure an unobstructed connection between the pulmonary venous return and the systemic right ventricle, and (3) to establish a reliable source of pulmonary blood flow. Although these goals are unchanged from those originally articulated by Norwood and colleagues in 1980, the methods by which these goals are achieved continue to evolve.

Standard Norwood Operation

The “standard” Norwood operation is performed through a median sternotomy. The branch pulmonary arteries are dissected and controlled. We routinely anastomose a 3.5-mm stretch Gore-Tex graft to the underside of the innominate artery. The graft may later serve as the right modified Blalock-Taussig shunt and is left long while it is used as the primary arterial cannulation site. Venous cannulation is performed in the right atrial appendage, through a purse-string suture large enough to allow subsequent atrial septectomy. The patient is cooled to 18° C and put on bypass, the ductus is divided, and the brachiocephalic vessels are mobilized and loosely snared. The main pulmonary artery is divided and the branch bifurcation is closed, primarily or with a patch. After at least 20 minutes of cooling and at a rectal temperature of 18° C, the brachiocephalic vessels are snared and the descending aorta is clamped. For truly diminutive aortas (<2 mm), cardioplegia is administered via a side arm into the arterial cannula, and direct needle insufflation is used in the larger aorta. We perform the Norwood operation during continuous regional low-flow perfusion, as previously described.⁴⁷⁻⁴⁹

The atrial septectomy is performed through a right atrial purse-string suture during a period of low-flow sucker bypass. The ductal remnant is amputated from the aorta, and the aorta is filleted open distally beyond the site of coarctation and proximally to a point adjacent to the lip of the transected pulmonary valve. The ductal insertion site is circumferentially resected, and the back wall of the aorta is sewn together, either directly or using an interdigitating technique. Proximally, a side-to-side anastomosis between the aorta and pulmonary valve is performed, and the arch is augmented using a piece of

FIGURE 128-2 ■ Technique of the Norwood operation. **A**, The pulmonary artery is transected and the bifurcation closed. The hypoplastic aorta is incised and ductal tissue excised. **B** and **C**, Graft material, usually pulmonary homograft, is cut to the appropriate size and shape for arch reconstruction. **D**, Inclusion of the pulmonary valve into the systemic circulation, with completion of the arch augmentation. **E**, Pulmonary blood flow is provided by the right modified Blalock-Taussig shunt. **F**, Anastomosis of the pulmonary artery to the arch; bypassing the diminutive ascending aorta is not recommended. Proximity of the very small ascending aorta to the shunt allows potential coronary steal and myocardial ischemia. In these cases, arch reconstruction should proceed as illustrated in **A**, or alternatively implanted into the side of the neo-aorta. (Reprinted with permission from Castañeda AR: Hypoplastic left heart syndrome. In Castañeda AR, Jonas R, Mayer JE, et al, editors: *Cardiac surgery of the neonate and infant*, Philadelphia, 1994, WB Saunders, p 371.)

pulmonary homograft or fixed autologous pericardium (Fig. 128-2). Central bypass is resumed after cannulation of the reconstructed aorta, and the pulmonary anastomosis of the shunt is completed.

Results of Norwood Operation

With experience and with advances in surgical, anesthetic, and critical care management, current survival of the Norwood operation approaches 90% at specialized centers.^{50,51} In one of the largest single-center series ever reported, Mahle and colleagues⁵² reported their 15-year (1984-1999) experience with the Norwood operation for 840 patients with HLHS. Of these 840 patients, 65% were male and 35% female, a gender ratio similar to that reported elsewhere. The 1-, 2-, 5-, 10-, and 15-year survival rates for the group were 51%, 43%, 40%, 39%, and 39%, respectively. Risk factors identified for death were earlier era of operation, age older than 14 days, and

weight less than 2.5 kg. Neither anatomic subtype nor heterotaxy was associated with mortality.

Because of the continuing evolution occurring among surgical and medical management techniques applied to HLHS, contemporary experience is important. Tweddell and colleagues⁵¹ reported their experience with 115 consecutive patients with HLHS who underwent the Norwood operation between 1992 and 2001. They reported that, with the introduction of new management techniques in 1996, they were able to obtain a 93% hospital survival rate for neonates undergoing the Norwood operation for HLHS. These strategies included the use of phenoxybenzamine, continuous systemic venous oxygen monitoring, aprotinin, modified ultrafiltration, and, most recently, continuous cerebral perfusion. This report is also of interest because it attempts to quantify the influence of anatomic and operative variables on survival to stage II palliation rather than on operative survival. Only duration of DHCA was associated with

survival to stage II palliation; no other anatomic or physiologic variable, including weight, was predictive.

A more recent review of the surgical experience of 237 patients undergoing stage I palliation at Children's Hospital Boston between 2001 and 2006 reported a hospital survival rate of 88.6%.⁵⁰ An arteriopulmonary shunt was used in 157 patients, and a right ventricle to pulmonary artery (RV-PA) conduit in 80 patients. Although the source of pulmonary blood flow did not impact hospital survival, the RV-PA conduit imparted a significant survival advantage during the interstage period (Fig. 128-3).

Anatomic Subtypes

Whereas previous studies^{16,17} reported a trend toward higher mortality rates among patients with aortic valve atresia, the Children's Hospital Boston review identified patients with aortic atresia *and* mitral stenosis to be a group at higher risk than other anatomic subtypes

FIGURE 128-3 ■ Conditional survival based on the source of pulmonary blood flow after stage I palliation. There was no perioperative difference in survival between the arteriopulmonary (Blalock-Taussig) shunt (BTS) or the right ventricle to pulmonary artery conduit (RVPA). However, the RVPA showed a significant survival advantage during the interstage period (interstage mortality: BTS 15% vs. RVPA 0%; $P = 0.014$).

FIGURE 128-4 ■ Era effect for mortality among hypoplastic left heart syndrome anatomic subtypes aortic atresia with mitral atresia (AA/MA), aortic atresia with mitral stenosis (AA/MS), and aortic stenosis with mitral stenosis (AS/MS). Although anatomic subtypes AA/MA and AS/MS have shown improved survival, subtype AA/MS lags behind.

(Fig. 128-4). Thirty-eight of 165 (23%) patients with HLHS had MS/AA. Hospital mortality and need for transplant for patients with MS/AA was significantly higher than for other anatomic subgroups (29% vs. 7.8%, $P = 0.006$; Fig. 128-5). Recently, we identified the presence of significant left ventricle to epicardial coronary artery fistula in these patients and, in one case, autopsy-proven aortocoronary atresia. A retrospective review of these patients identified echocardiographic evidence of coronary artery fistulas in 20 patients (53%) with MS/AA. The presence of suggestive echocardiographic findings was associated with a greater hospital mortality (50% vs. 6%, $P = 0.04$; Fig. 128-6). It is among this cohort of patients that the increased risk seems to be isolated; patients with MS/AA without evidence of fistulas demonstrated survival similar (94%) to other anatomic subtypes (aortic atresia–mitral atresia [AA/MA], 8.6%, and aortic stenosis–mitral stenosis [AS/MS], 7.2%; $P = 0.9$). Although these findings were originally interpreted as small muscular ventricular septal defects, cardiac catheterization has

FIGURE 128-5 ■ Likelihood of survival for patients with aortic atresia with mitral stenosis (AA/MS) variant as compared with other subtypes of hypoplastic left heart syndrome. Overall survival is significantly worse for AA/MS ($P = 0.042$).

FIGURE 128-6 ■ Hypoplastic left heart syndrome (HLHS), anatomic subtype aortic atresia with mitral stenosis (AA/MS). Analysis (echocardiographic of angiographic) showed left ventricle to coronary artery fistulas to be a highly significant risk factor for death after stage I palliation for HLHS. Risk appears to reside in this subgroup (mortality, 50%) because mortality for patients with AA/MS without fistulas is similar to that for other anatomic subtypes (approximately 6%, $P = 0.0001$).

FIGURE 128-7 ■ Diagnosis of left ventricle to coronary artery fistulas. **A**, Echocardiographic examinations often reveal flow “across” the interventricular septum and have been considered to represent ventricular septal defects. **B**, Angiographic demonstration of left ventricle to coronary artery fistulas with retrograde filling of the ascending aorta in addition to the right coronary artery system. **C**, Intraoperative examination has consistently revealed a small “duvet” or “pucker” in the myocardium, presumably at the site of the fistulas, with a thickened and corkscrew appearance of the epicardial coronary artery.

clearly identified left ventricle to coronary artery fistulas in these patients (Fig. 128-7). No advantage to the arteriopulmonary shunt or the Sano modification has been identified for these patients. The exact mechanisms for the increased failure of stage I palliation in patients with AA/MS and fistulas is still unclear. We hypothesize that the presence of fistulas may contribute to dysfunction of the interventricular septum in these marginal patients. However, this remains to be proven.

Based on this experience, we have changed our institutional policy regarding the preoperative evaluation of these patients. Patients identified as being in the AA/MA subtype undergo preoperative angiography to confirm and define the incidence of left ventricle to coronary artery fistulas. In the past, many of these patients were diagnosed, by echocardiogram, with small ventricular septal defects, but in fact these echocardiographic findings most likely represent a left ventricle to coronary artery fistula. If these patients are confirmed as a high-risk group, alternative treatment pathways, such as the hybrid stage I palliation or primary transplantation, may be considered.

Source of Pulmonary Blood Flow

Surgeon experience and institutional preference have been cited as reasons for choosing the source of pulmonary blood flow after the Norwood procedure.⁵³⁻⁵⁵ A prospective, multi-institutional randomized study was performed with the primary outcome death or cardiac transplantation 12 months after randomization.⁵⁶ Transplant-free survival at 12 months was greater in the patients who underwent an RV-PA conduit; however, this group had more unintended interventions and complications. Right ventricular size and function were similar within both cohorts. At 12 months of age to study completion, there was no difference in survival or transplant-free survival between the groups. Mid-term analysis of these data is currently being performed to identify if these conclusions remain true.

Interstage and Mid-term Survival

Of the 188 survivors discharged from the hospital after stage I palliation, 20 (10.6%) died in the interstage period. The median age at interstage mortality was 75 days, and it occurred exclusively in patients with an arteriopulmonary shunt (see Fig. 128-3). The cumulative pre-Glenn mortality (hospital + interstage) rate was 19.8% (47 of 237).

Low Birth Weight, Older Age

Low birth weight (<2.5 kg), consistently identified as a risk factor, was the subject of a subanalysis performed by Weinstein and colleagues.⁵⁷ They reported a 47% survival rate among 67 patients weighing less than 2.5 kg who underwent the Norwood operation between 1990 and 1997. Although lower than the institution's overall survival rate of 74%, these results are very similar to those reported by Bove and Lloyd, Forbess and colleagues, and others.⁵⁸⁻⁶⁰ Although the patients were higher risk, there was no appreciable weight gain in neonates awaiting surgery, and the authors concluded that delaying surgery in the hope of somatic growth is unwarranted.

Whereas some reports have demonstrated poorer survival when Norwood palliation is performed after 2 to 4 weeks of life, recent reports suggest otherwise. Duncan and colleagues⁶¹ reported 100% survival among 9 patients, aged 36 to 108 days, who underwent palliation for single-ventricle variants. Reviewing their experience with the Norwood operation for HLHS, Rossi and others⁶² reported a 90% survival rate among patients older than 2 weeks of age; 100% (4 of 4) of those older than 4 weeks survived.

Norwood Operation for Hypoplastic Left Heart Syndrome Variants

Although the Norwood operation was devised specifically to treat HLHS, it has been widely applied to various

BOX 128-1 Anatomic Variants of the Great Vessels, for Which the Norwood Operation Is Performed

NORMALLY RELATED GREAT VESSELS

- Mitral atresia with ventricular septal defect (VSD)
- Mitral atresia and aortic stenosis with VSD and small left ventricle
- Interrupted aortic arch with severe subaortic obstructions
- Unbalanced atrioventricular septal defect

ABNORMALLY RELATED GREAT VESSELS

- Double-inlet left ventricle with D-transposition of the great arteries
- Tricuspid atresia, VSD, transposition
- Complex double-outlet right ventricle with arch hypoplasia

forms of congenital heart disease that show systemic outflow tract obstruction and a duct-dependent systemic circulation. Because of the impact of great vessel relationships on arch reconstruction, it is useful to define these variants as those that present with normal versus abnormal relationships between the great arteries (i.e. transposition complexes) (Box 128-1).

Surgical Results for Hypoplastic Left Heart Syndrome Variants

Whereas some groups have identified the presence of a well-developed morphologic left ventricle as being protective, others have not.^{63,64} A recent comparison of the Norwood operation performed for HLHS (102 patients, 70 with aortic atresia) and other diagnoses (56 patients) between 1998 and 2001 by Gaynor and colleagues⁶⁵ identified no difference in survival between the Norwood operation for HLHS versus other anatomic diagnoses (78% vs. 75%).

Although the presence of abnormally related great arteries has not been identified as a risk factor for mortality, they may render the constructed neoarch susceptible to twists or kinks, and modifications may be required (Figs. 128-8 and 128-9).⁶⁶

Extracorporeal Membrane Oxygenation for Hypoplastic Left Heart Syndrome

Once thought to be futile, perioperative support with extracorporeal membrane oxygenation (ECMO) may salvage a significant proportion of infants with post-cardiotomy failure following the Norwood operation. Pizarro and colleagues⁶⁷ reported that 50% (6 of 12) of patients requiring ECMO support following Norwood operation were discharged home in good condition. Prematurity, renal dysfunction, and the initiation of ECMO outside of the operating room were risk factors for death. In the setting of a shunt-dependent circulation, Jaggers and colleagues⁶⁸ have reported improved survival when the shunt is left open during ECMO support.

FIGURE 128-8 ■ **A**, Single left ventricle with ventriculoarterial discordance and a rightward and anterior aorta. The atrial septum is excised, and both great vessels are transected just about at the sinotubular junction. Augmentation of the arch is accomplished with pulmonary homograft. **B**, A side-to-side anastomosis between the aorta and pulmonary artery is fashioned. The reconstructed aorta is then anastomosed to both great vessels in an end-to-end fashion. (Reprinted with permission from Mosca RS, Hennein HA, Kulik TJ, et al: Modified Norwood operation for single left ventricle and ventriculoarterial discordance: an improved surgical technique. *Ann Thorac Surg* 64:1126–1132, 1997.)

Modifications

The gradual improvement in survival for the Norwood operation is the result of continuous reappraisal of our surgical and management techniques. Bartram and colleagues⁶⁹ performed a systematic review of the causes of surgical mortality of 122 patients undergoing the Norwood operation between 1980 and 1995. Although this review is historical in nature, it deserves attention because it identifies the weaknesses of this operation.

Bartram and colleagues⁶⁹ reported that inappropriate pulmonary blood flow (too much or too little) was responsible for 36% of the deaths. The second most

FIGURE 128-9 ■ Operative technique for abnormally related great arteries as might be seen with single left ventricle and transposed great arteries, with the aorta anterior and leftward. **A**, Ligation of ductus and lines of incision. **B**, Closure of the pulmonary artery bifurcation. **C**, Overlapping incisions in ascending aorta and the arch. Augmentation is accomplished with separate patches. **D**, Completed reconstruction. (Reprinted with permission from Jacobs ML, Rychik J, Murphy JD, et al: Results of Norwood's operation for lesions other than hypoplastic left heart syndrome. *J Thorac Cardiovasc Surg* 110:1555–1562, 1995.)

common cause of death was impaired coronary perfusion, occurring in 27% of patients, followed by neo-aortic obstruction (14%), right ventricular failure (13%), and bleeding (7%). Other groups have identified an association between the duration of DHCA and both short and intermediate survival.⁵¹ Modifications have been introduced into the procedure that attempt to nullify these weaknesses.

Control of Pulmonary Blood Flow. Control of pulmonary blood flow by pharmacologic titration of the systemic vascular resistance represents a fundamental shift in the management of palliated single ventricles. This approach has been reported to assist in balancing the pulmonary and systemic circulations and improving systemic oxygen delivery.^{51,70} This approach appears to contribute to improved survival of neonates undergoing the Norwood operation for HLHS.

Coronary Circulation. Because of systemic runoff into the pulmonary circulation via the arteriopulmonary shunt, the myocardium is vulnerable to coronary steal and ischemia after the Norwood operation.⁷¹ A technical

modification of the Norwood operation designed to reduce the vulnerability of the myocardium to ischemia was proposed by Imoto and colleagues.⁷² They reasoned that with placement of shunt inflow proximal to the semilunar (pulmonary) valve, the coronary circulation would be protected from the low diastolic blood pressures that accompany continuous diastolic runoff.

In general, this technique uses a 5- or 6-mm Gore-Tex conduit anastomosed proximally to the infundibulum of the right ventricle, coursing leftward of the pulmonary valve. The conduit is then inserted into the patch (Gore-Tex or pericardium) used to repair the pulmonary bifurcation. One technical point to be stressed using this technique is excision of right ventricle muscle at the site of insertion, because muscular ingrowth with the anticipated right ventricle hypertrophy may obstruct the conduit. Variations of this technique, interposing a valved segment of human saphenous vein between the right ventricle and pulmonary artery, have also been reported.⁷³

Early clinical results have been encouraging. Malec and colleagues⁷⁴ documented higher mean diastolic blood pressures in patients receiving the RV-PA conduit. Although preliminary data based on hemodynamic data

obtained prior to stage II suggests that these patients will be excellent candidates for subsequent surgical staging; the long-term sequelae of a ventriculotomy in this setting remain unknown.⁷⁵

Arch Modifications. Neoaortic obstruction is an important complication of the Norwood operation, occurring in approximately 20% of patients.^{76,77} Azakie and colleagues⁷⁸ related this complication to the size of the ascending aorta (<3 mm). Machii and Becker⁷⁹ suggested that longitudinal and circumferential extension of ductal tissue into the aorta also contributes.

Despite the high incidence of recurrent coarctation, the diagnosis may remain elusive. The reliability of neonatal echocardiography is degraded as a result of thymic resection, as well as the variable position of the reconstructed aorta. Given the morbidity and mortality associated with postoperative arch obstruction, inconclusive or suggestive echocardiographic and clinical examinations are an indication for cardiac catheterization. Because arch gradients are influenced by multiple factors, including the presence of an arteriopulmonary shunt, vascular resistances, and cardiac output, we tend to aggressively treat even minor gradients. If imaging suggests a significant caliber discrepancy across the aortic arch, treatment (either catheter or surgical) of the arch is strongly considered, even in the presence of a minor gradient (5 to 10 mm Hg).

Both surgical and interventional techniques designed to reduce neoaortic arch obstruction have been introduced. Fraser and Mee⁸⁰ reported the technique of using a direct anastomosis of the pulmonary artery to the aortic arch (Fig. 128-10). The operative survival rate was 83% among 59 patients with a median follow-up of 37 months; the incidence of neoaortic arch obstruction was only 5%. These authors and others have suggested that patients with very small ascending aortas (≤ 2.5 mm) are at a higher risk undergoing this technique and have suggested several modifications to nullify the risk in these patients.^{81,82}

In a review by Bautista-Hernandez and colleagues,⁸³ circumferential coarctectomy was found to reduce the incidence of neoaortic arch obstruction after stage I palliation. In addition, patients undergoing arch reconstruction using only autologous tissue (fixed pericardium or direct pulmonary artery to aorta anastomosis) were found to be less likely to require intervention for arch obstruction than were patients reconstructed with homograft material. More aggressive techniques of arch reconstruction, such as the interdigitation technique, have been adopted by some groups (personal communication). One of these techniques uses a counter-incision along the greater curvature on the descending aorta, into which the opened transverse arch is inserted. The entire arch is then augmented using standard techniques.

Recoarctation: Catheter Intervention. Soongswang and colleagues⁸⁴ reported a multi-institutional experience with transcatheter balloon dilation of the neoaorta following the Norwood operation in 58 patients. Although the operation was successful in 89% of patients, there were 3 early and 10 late deaths, 9 patients required

FIGURE 128-10 ■ Modifications to the Norwood procedure have resulted in a reduced incidence of arch obstruction. This technique is probably unsuitable for a very small ascending aorta (≤ 2.5 mm). (Reprinted with permission from Poirer NC, Drummond-Webb JJ, Hisamochi K, et al: Modified Norwood procedure with a high-flow cardiopulmonary bypass strategy results in low mortality without late arch obstruction. *J Thorac Cardiovasc Surg* 120:875-884, 2000.)

reintervention for arch obstruction (6 catheter, 3 surgical), and freedom from reintervention was 78% at 1 year.

Perfusion Management. Studying 350 neonates between 1992 and 1997, Clancy and colleagues⁸⁵ reported that the duration of DHCA was an independent risk factor for death. Among patients undergoing the Norwood operation, data reported by Tweddell and coworkers⁵¹ suggest that DHCA exposure was associated with interstage mortality. DHCA was once considered unavoidable for neonatal aortic arch reconstruction; however, newer techniques have allowed a dramatic reduction, even elimination of the need for DHCA (Fig. 128-11).⁴⁷⁻⁴⁹ The benefits of this approach remain unclear; two studies to date have not identified an advantage (as

FIGURE 128-11 ■ Operative field during aortic arch reconstruction during regional low-flow perfusion. Arterial inflow is through the cannulated shunt after the anastomosis to the innominate artery is performed. Exposure is maintained by the brachiocephalic snares, a clamp on the descending aorta, and a right atrial scavenger. When using this technique for arch reconstruction in the setting of a two-ventricle repair, or when incorporating the right ventricle to pulmonary artery conduit into the Norwood procedure, the shunt is oversewn on completion of the procedure.

measured by survival and neurodevelopmental outcomes at 1 year of age) to using regional perfusion of the brain during stage I palliation.^{86,87}

Interstage Mortality

Although the efforts described in this chapter have translated into improved survival following the Norwood operation, the palliated state renders these patients physiologically fragile. This vulnerability is thought to be responsible for an interstage mortality rate ranging between 4% and 15%.^{51,78,88}

To date, the only operative variables associated with interstage mortality is longer duration of DHCA⁵¹ and the presence of an arteriopulmonary shunt.⁵⁰ Recent initiatives, such as the development of home monitoring programs and/or anticoagulation protocols, may also be helpful. Although earlier progression to stage II will reduce the period of vulnerability, this approach is limited by the rate of decline in pulmonary vascular resistance. Reporting their experience with early Glenn operations, Reddy and colleagues⁸⁹ reported a reoperation rate of 17%; reoperation was more likely among patients younger than 2 months of age. In general, postponement of the bidirectional Glenn until 3 months of age is preferable.

STAGE II

Originally, survivors of the Norwood operation were staged directly to the Fontan operation within the first year of life. It was soon recognized, however, that this approach resulted in significant morbidity and mortality.⁹⁰ Consequently, the insertion of an intermediate stage, the superior bidirectional cavopulmonary anastomosis (bidirectional Glenn or hemi-Fontan), was introduced by Jacobs and Norwood and resulted in improved survival.⁹¹

Stage I survivors are generally evaluated at 4 to 6 months for progression to stage II. Anatomically, the adequacy of the arch reconstruction, the branch pulmonary arteries, and intra-atrial communication should be assessed. Physiologically, catheterization is helpful to assess ventricular function and pulmonary vascular resistance.

Operative Technique

Bidirectional Glenn

The neck and the chest are prepared and draped. In the advent of cavitory entry, the right neck provides ready access for peripheral cannulation. Following cannulation of the ascending aorta and with venous cannulas in the high superior vena cava and right atrial appendage, the patient is cooled to between 30° C and 32° C. We prefer to perform a bidirectional Glenn operation with the heart beating. After division of the azygous vein, the superior vena cava is clamped at its insertion into the right atrium just above the sinoatrial node and transected, and the atrial orifice is oversewn. The pulmonary remnant of the Blalock-Taussig shunt is excised, and the pulmonary arteriotomy is enlarged to accommodate the superior vena cava. The anastomosis is performed with an absorbable 7-0 suture taking care not to purse-string the anastomosis. The patient is rewarmed, ventilated, and weaned from cardiopulmonary bypass. Saturations in the range of 70% to 85% with superior vena cava pressure of 10 to 12 mm Hg, with an atrial pressure of 5 to 6, are expected. Superior vena cava pressures exceeding 16 or a transpulmonary gradient exceeding 8 to 10 mm Hg should prompt critical appraisal of the anastomosis.

Hemi-Fontan

Introduced by Jacobs and Norwood⁹¹ in 1989, the hemi-Fontan operation is the preferred form of superior cavopulmonary anastomosis for some groups. Briefly, the central pulmonary arteries are opened anteriorly and anastomosed to a counter-incision along the base of the right atrial appendage. Separate patches are then used to augment the central pulmonary arteries, as well as to exclude the superior vena cava–pulmonary artery anastomosis from the heart. Although some surgeons have reported improved survival of the Fontan procedure following the hemi-Fontan as compared with the bidirectional Glenn, this is not uniform.^{92,93}

This modification differs from the bidirectional Glenn in several important ways. Because an intra-atrial patch

FIGURE 128-12 ■ Stage II, hemi-Fontan operation for hypoplastic left heart syndrome. **A**, The pulmonary arteries are opened anteriorly. **B**, The superior vena cava and the right pulmonary artery are anastomosed side to side. **C**, Flow from the superior vena cava is into the pulmonary arteries, as indicated by the arrows (**D**). (Reprinted with permission from Jacobs ML: Hypoplastic left heart syndrome. is required to exclude the superior cavopulmonary anastomosis from the heart, cross-clamping of the aorta is required; some surgeons use a period of DHCA (Fig. 128-12A, B).⁹⁴ Furthermore, intra-atrial suture lines, implicated in the genesis of atrial arrhythmias, are required.⁹⁵

Results of Stage II

Regardless of which technique is preferred, the results of the stage II procedure have been reproducibly excellent, exceeding 95% in large series.^{58,96} Assessments of longer-term complications (e.g., sinus node dysfunction and arrhythmias) are more difficult. Although Cohen and colleagues⁹⁶ reported a higher incidence of sinus node dysfunction on postoperative day 1 in patients undergoing hemi-Fontan as compared with bidirectional Glenn, there was no difference by the time of hospital discharge. Furthermore, at the time of subsequent Fontan, the authors reported no difference in early sinus node dysfunction.

FONTAN

The Fontan operation is destination therapy for HLHS (Fig. 128-13). By diverting all systemic venous return to

the pulmonary circuit, physiologic septation of the circulation is accomplished.⁹⁷ Although HLHS has been cited as a risk factor for early Fontan failure, other reports place early survival of Fontan for HLHS as high as 98%.^{93,98} Exercise performance among HLHS patients undergoing Fontan appears to be comparable to other single-ventricle variants.⁹⁹

Since its introduction in 1971, the Fontan operation has undergone a steady evolution. Progressive atrial dilation and atrial arrhythmias led to modifications of the original operation, first to the lateral tunnel technique and then to the extracardiac conduit. Experimental data suggest that the extracardiac conduit is superior to the lateral tunnel with respect to energy efficiency. Comparing the intra-atrial lateral tunnel, the extra-atrial lateral tunnel, and the extracardiac conduit, Lardo and coworkers¹⁰⁰ found the extracardiac conduit to be most hydrodynamically efficient.

Short-term clinical advantages, including postoperative arrhythmias, shorter intensive care unit (ICU) stays, and earlier extubations, have also been reported.¹⁰¹ Although few long-term data are available, there appears to be an important reduction in atrial arrhythmias over the intermediate term.^{100,102} Also, the extracardiac Fontan may provide important versatility when addressing certain anatomic subsets, notably the heterotaxy variants presenting with systemic venous abnormalities. In these

FIGURE 128-13 ■ Stage III, completion Fontan for hypoplastic left heart syndrome. **A**, The hemi-Fontan. **B**, The previously placed homograft separating the right atrium from the superior vena cava is excised. **C**, Total cavopulmonary connection is accomplished using the lateral tunnel technique. circumstances, unifocalization of the inferior systemic venous return to an extracardiac conduit may greatly simplify the completion Fontan. Potential disadvantages of the extracardiac conduit Fontan, including thrombogenicity and lack of growth potential, remain to be assessed over the long term.

TRANSPLANTATION

Whereas most centers have devoted their efforts to surgical palliation using the Norwood operation, a few groups have concentrated on neonatal transplantation as the primary treatment. The technical details of heart transplantation for HLHS have been well described.^{101,103}

The Loma Linda group reported their experience with heart transplantation as the primary treatment for HLHS.¹⁰⁴ Between 1985 and 1995, 190 infants with HLHS were listed for heart transplant. Actuarial survival rates at 1, 5, and 7 years were 84%, 76%, and 70%, respectively; 14 patients were delisted, and 34 of the remaining 176 (19%) patients died while awaiting transplant. Inclusion of these 34 patients listed with the intent to transplant lowers the survival of transplantation to 74% (129 of 176). Year of transplantation was not a risk factor for death. Outcomes for transplantation versus Norwood operation, on an intent-to-treat basis, were reported by Jenkins and colleagues.¹⁰⁵ Examining 231 patients born between 1989 and 1994, they reported that

transplantation resulted in greater survival through 7 years of follow-up. Multivariate analysis identified birth weight less than 3 kg, creatinine level of 2 mg/dL or higher, and atrial septostomy as significant risk factors for death in both groups.

A decision analysis performed on the same patients found that regional and local factors, such as organ availability and institutional dedication to a particular treatment, imparted a powerful influence on outcome.¹⁰⁴ Also, it is difficult to assess the rate at which improvement can be expected among the competing strategies. For example, Jenkins and colleagues¹⁰⁶ reported 1-year survival of the Norwood operation to be only 42% between 1989 and 1994, significantly lower than more contemporary results (66%, 1996 to 2001). In contrast, Razzouk and colleagues¹⁰⁷ did not correlate improved operative survival among patients transplanted between 1985 and 1995.

Finally, competing long-term complications of each strategy remains to be considered. For example, it does not appear that children are particularly privileged with respect to transplant complications; up to 35% of pediatric transplant recipients will develop diffuse graft arteriosclerosis, for which re-transplantation may be required.^{104,108,109}

In part because of the special needs of a neonatal heart transplant program, the ongoing risk of transplant-related complications, and continued improvements in staged outcomes, staged surgery for HLHS has become the primary treatment offered at most institutions. However, transplantation for specific indications, such as coronary abnormalities and valvular disease, remains an important treatment option.

NEURODEVELOPMENTAL OUTCOMES

With improving survival after the surgical treatment for HLHS, a broader, long-term assessment of neurologic outcomes has assumed a new prominence. Although studies are impaired by methodologic difficulties, most indicate that DHCA is detrimental to ultimate neurodevelopmental outcome.¹¹⁰ Kern reported a negative correlation between stage I circulatory arrest time and full scale IQ, an average of 4.4 years after the Norwood operation.¹¹¹

These deficits appear to persist. Mahle and colleagues¹¹² assessed the neurodevelopmental outcome of 115 survivors of the Norwood operation at an average age of 9 years. They reported a mean IQ of 86 (range, 50 to 118) with 18% meeting criteria for mental retardation (IQ < 70). Only 3 of 23 (13%) were thought to have completely normal neurodevelopment.

When compared with children undergoing a Fontan operation for other indications, patients with HLHS demonstrated significantly lower intelligence scores than did their counterparts; the use of circulatory arrest was identified as a predictor.¹¹³ As mentioned, use of regional perfusion techniques have failed to show improved neurodevelopmental outcomes, and emerging data suggest that these children have abnormal cerebral circulatory patterns and preexisting cerebral lesions at the time of birth. As such, modifications of intraoperative variables

may have little impact on a predestined neurologic outcome.

HYBRID PROCEDURES

Ductal stenting and bilateral pulmonary artery banding for HLHS ("hybrid" procedure) was introduced in 1993 by Gibbs and colleagues.¹¹⁴ This approach has been extended and modified by others and, in select centers, constitutes the preferred management scheme for patients with HLHS. A review by Galantowicz and Cheatham¹¹⁵ described their experience with 29 neonates with HLHS between 2001 and 2004. They describe a comprehensive hybrid strategy for the treatment of HLHS. Following ductal stenting and bilateral pulmonary artery banding, patients undergo a comprehensive stage II procedure, which consists of aortic arch repair, repair of the branch pulmonary arteries, surgical atrial septectomy, and a modified bidirectional Glenn operation. This procedure is considered comprehensive by virtue of the fact that it is anticipated to be the only open-heart procedure required for staging to the Fontan circulation. The bidirectional Glenn operation is modified by anastomosing the open-ended stump of the superior vena cava attached to the right atrium to the underside of the right pulmonary artery. A patch of pericardium is sewn over the superior vena cava and right atrium orifice inside the right atrium to separate the circulations.

At the time of stage III (Fontan operation), the pericardial patch is perforated and dilated using catheter techniques via the right internal jugular vein. A covered stent is placed between the inferior vena cava and superior vena cava orifice, completing septation of the circulation. Alternatively and more recently, an extracardiac Fontan is often used, avoiding myocardial arrest.

A surgeon and institutional learning curve was initially seen with adoption of the hybrid technique.¹¹⁵ Galantowicz and colleagues have prospectively reported on 40 patients who underwent a hybrid Norwood procedure. Overall survival through the second stage of palliation was 83%, comparable to the traditional Norwood strategy.¹¹⁶ More recently, centers with a well-established Norwood program adopting the hybrid procedure are able to achieve results comparable to those with the traditional Norwood pathway.^{117,118}

An important risk factor identified is the presence of a retrograde aortic arch obstruction; identified as a "3" sign on echocardiogram, it is most associated with aortic atresia.¹¹⁹ If a retrograde aortic arch obstruction is identified at birth or early interstage, a traditional Norwood operation is recommended over a hybrid approach. Banding of the pulmonary arteries in the neonatal period was shown to require an increased need for pulmonary artery interventions but did not show worse hemodynamics and did not decrease Fontan candidacy.^{120,121} Because of these results, some centers recommend angiograms on completion, and early intervention, sometimes at the time of surgical intervention, is recommended.¹²²

Initial enthusiasm of the hybrid procedure, avoiding cardiopulmonary bypass and myocardial arrest, has not

shown less interstage ventricular dysfunction or atrioventricular valve regurgitation.¹²³ Additionally, gastrointestinal complications after a traditional Norwood procedure were no greater than after a hybrid procedure.^{124,125}

The fragile nature of the palliated circulation in these children requires frequent interstage evaluations (every 1 to 2 weeks), with liberal use of screening echocardiograms to assess ventricular function and developing obstruction through the ductal stent, aortic arch, or pulmonary arteries. Based on echocardiographic findings and physical examination, cardiac catheterization to confirm and treat stenosis with redilation has been an important adjunct.

EMERGING THERAPIES

Fetal Intervention

Since March 2000, fetal intervention for evolving HLHS has been pursued in selected fetuses at Children's Hospital Boston. Qualification criteria have been previously published.¹²⁶ The lesions targeted in this disease are the stenotic aortic valve and the intact atrial septum.

Since 2000, 42 fetuses with HLHS in evolution underwent attempted aortic valvuloplasty,¹²⁷ the technical aspects of which have been described in detail previously.^{127,128} Among 26 fetuses that underwent technically successful in utero aortic valvuloplasty, 8 achieved a biventricular circulation postnatally. All of these fetuses had improved Doppler flow characteristics across the aortic valve on follow-up fetal echocardiography. The other 18 patients with a technically successful procedure were managed postnatally with a strategy of single-ventricle palliation, as were the 4 patients in whom fetal aortic valvuloplasty was technically unsuccessful and the 14 control patients who did not undergo fetal intervention.

The only factors that differed significantly between groups were postintervention left ventricular ejection fraction ($48\% \pm 18\%$ in fetuses that underwent biventricular repair and $34\% \pm 11\%$ in those that did not; $P = 0.03$) and presence of antegrade flow in the transverse arch, which was found in all 8 patients who had a biventricular repair and 9 of 18 that underwent single-ventricle palliation ($P = 0.02$) (Fig. 128-14).

As described earlier, although fetal intervention for HLHS with intact atrial septum has shown a trend toward improved hospital survival (3 of 14, 21%, versus 7 of 18, 39%; $P = 0.45$) and 6-month survival (69% vs. 38%; $P = 0.2$), the experience is too small to be conclusive.

Regardless of the lack of conclusive evidence, the early experience would seem to justify continued efforts at prenatal and postnatal efforts to rehabilitate the left ventricle as a contributor to the circulation. Although the ultimate goal of a septated biventricular circulation may not be attainable in all cases, any contribution to the combined ventricular output from the left ventricle would be a welcome contribution to the Fontan circulation in patients requiring single-ventricle palliation.

FIGURE 128-14 ■ Anatomic recruitment of the hypoplastic left ventricle into the systemic circulation. Staged intervention suggests that the postnatal left ventricle retains some capacity for growth. **A**, Echocardiogram of newborn with hypoplastic left heart syndrome, showing a hypoplastic left ventricle and thickened endocardium, consistent with endocardial fibroelastosis (EFE). **B**, Echocardiogram of the same child at age 22 months. The child was treated with stage I palliation, including EFE resection, followed by bidirectional Glenn operation with further EFE resection before subsequently undergoing successful biventricular repair at age 22 months.

Heart Transplantation

Mechanical Circulatory Support

COMPUTER MODELING TO OPTIMIZE FONTAN ENERGETICS

Single-ventricle circulation is a generic term that covers a wide range of structural cardiac abnormalities. It is widely accepted that the definitive surgical palliation for these hearts is the Fontan circulation, whereby the pulmonary and systemic blood flows are in series with the single ventricle connected to the systemic circulation. To optimize clinical outcomes with the Fontan, many patients need prior interventions to adjust the pulmonary or systemic circulation. Because of the changing physiology in the early years of life, a series of operations is often necessary.

TERMINOLOGY AND ANATOMY

In this chapter, the term *single ventricle* refers to congenital cardiac malformations that lack two completely

well-developed ventricles in which functionally there is only a single ventricular chamber that supports both the pulmonary and systemic circulations. A truly morphologic univentricular heart is rare; more often there is an additional rudimentary chamber. Over the years, numerous classifications and terms for these hearts have emerged. The Congenital Heart Surgery Nomenclature and Database Project minimum data set categorized single ventricles into seven broad categories¹: hearts with common inlet atrioventricular connection (double-inlet right ventricle and double-inlet left ventricle), hearts with absence of one atrioventricular connection (tricuspid atresia and mitral atresia), hearts with common atrioventricular valve and only one well-developed ventricle (unbalanced common atrioventricular canal defect), hearts with only one fully developed ventricle and heterotaxia syndrome (single-ventricle heterotaxia

syndrome), and other rare forms of univentricular hearts that do not fit in one of these categories. A more comprehensive classification of the Congenital Heart Surgery Nomenclature and Database Project subclassifies these categories of single ventricle into four hierarchies spanning more than three printed pages.² Tricuspid atresia is the most common type of single ventricle, with an incidence of 1% to 3% of all congenital heart lesions.

In addition, there are some cardiac abnormalities in which, in the presence of two well-developed ventricles, the anatomy precludes biventricular repair. Examples include hearts with major straddling of the atrioventricular valve and double-outlet right ventricle with remote ventricular septal defect. Treatment strategies for these nonseptatable hearts are the same as those applied to univentricular hearts.

The management of hypoplastic left heart syndrome, a common form of univentricular heart with a dominant right ventricle and rudimentary left ventricle is not discussed in this chapter. [Chapter 128](#) is dedicated to this topic.

NATURAL HISTORY

Patients born with a single functional ventricle generally have a dismal long-term prognosis without eventual surgical intervention. Current results of the Fontan procedure as the final palliative surgical procedure for these patients are generally good, but it must be recognized that management of these patients begins at birth if they are to be satisfactory candidates for the Fontan procedure. The natural history of single-ventricle circulations is greatly influenced by the degree of pulmonary blood flow and associated lesions, such as coarctation of the aorta, systemic outflow tract obstruction, and anomalies of pulmonary or systemic venous return. In addition, noncardiac abnormalities may be present.

Severe obstruction to pulmonary blood flow at birth is an important determinant for early death. Patients with unobstructed pulmonary flow can develop congestive heart failure in infancy or later, and, if unoperated, can develop pulmonary vascular disease. The clinical course may be worsened by the presence of left-sided obstructive lesions such as coarctation of the aorta. In a small subset of patients, the pulmonary and systemic circulations are well balanced because of unrestricted systemic blood flow and sufficient pulmonary obstruction to control pulmonary blood flow. These patients have a more favorable life expectancy. The aim of surgical intervention is to improve the natural history by balancing blood flow between the pulmonary and systemic circulations and ultimately separating these circulations. In addition, other significant hemodynamic abnormalities should be corrected.

CLINICAL PRESENTATION AND PREOPERATIVE EVALUATION

Clinical presentation is determined by the amount of pulmonary blood flow and the associated cardiac lesions.

Patients with restricted pulmonary blood flow will exhibit cyanosis. Some may have a duct-dependent pulmonary circulation and will become rapidly cyanosed as the ductus arteriosus closes after birth. In the case of a large left-to-right shunt, the patient will present with congestive heart failure. Symptoms will deteriorate with falling pulmonary resistance in the first weeks after birth. Although in most single ventricles there is mixing of circulations, streaming may occur, particularly in complex hearts, resulting in differential saturations in the great arteries.

A precise anatomic diagnosis is essential to allow proper planning of the surgical procedures. In particular, information on the size and course of the pulmonary arteries, degree of pulmonary blood flow, and presence of accessory lesions is required, as well as an assessment of cardiac function. History, clinical presentation, chest x-ray, and electrocardiogram offer important but nonspecific information. Echocardiography provides detailed information on the structure and function of the heart and has the advantage that it is a noninvasive investigation that can be performed at the bedside. In particular, in infants who have excellent echocardiographic windows, enough information often can be gathered to proceed to operation. Cardiac catheterization is uncommonly needed to evaluate pulmonary vascular resistance or accessory sources of pulmonary blood flow. Interventional procedures, such as balloon atrial septostomy for restrictive atrial communication in hearts without two well-formed atrioventricular valves, can be carried out to supplement, or sometimes replace, surgical treatment.

SURGICAL PREPARATION FOR THE FONTAN CIRCULATION

Because the ultimate success of the Fontan operation depends on a suitably low pulmonary vascular resistance and adequate pulmonary artery architecture, it is critical to commence the preparation for a Fontan procedure in the newborn period by appropriately regulating pulmonary blood flow. There is a wide variation in the distribution of pulmonary and systemic blood flow in patients with single-ventricle circulation. Some patients have restricted pulmonary blood flow, others have unrestricted pulmonary flow, and a few have a naturally balanced circulation. Most patients, therefore, require palliative procedures leading up to the Fontan circulation, either to restrict or to augment pulmonary blood flow. The choice of procedure is guided by the underlying anatomy and pulmonary vascular resistance, both of which are subject to change over time. It should always be borne in mind that improper palliative procedures can result in the loss of Fontan candidacy. The ultimate goal of surgical procedures leading up to the Fontan circulation are to (1) improve clinical symptoms, (2) provide optimal pulmonary artery architecture and low pulmonary vascular resistance, (3) preserve systolic and diastolic ventricular function, (4) preserve atrioventricular valve function, (5) relieve systemic ventricular outflow tract obstruction, and (6) provide anatomic setup for a definitive Fontan repair.

Inadequate Pulmonary Blood Flow

In the neonatal and early infantile period, when pulmonary vascular resistance is still high, if the child is ductal dependent or has inadequate systemic oxygen saturations, a systemic to pulmonary artery shunt, usually a modified Blalock-Taussig shunt, is performed.³ Although this was classically performed through a thoracotomy approach, a sternotomy is now commonly used because it allows for concomitant ductal ligation and correction of stenosis of the proximal left pulmonary artery if present.^{4,5} Despite decades of experience with the modified Blalock-Taussig shunt, there remains a persistent early and intermediate morbidity and mortality with this procedure.⁶

Excessive Pulmonary Blood Flow

In the case of excessive pulmonary blood flow, it is imperative to limit the pulmonary blood flow to protect the patient from developing pulmonary vascular disease and ventricular dysfunction as a result of chronic volume overload.⁷ Adequate tightness of a pulmonary artery band can be difficult to achieve, and a band that is too loose initially can result in unprotected pulmonary arteries until the child grows into the band. The resultant pulmonary vascular disease may affect the ultimate suitability of the child for the Fontan procedure. Other complications of pulmonary artery banding include distortion of the pulmonary arteries, especially if the band migrates, and erosion of the band. Because of the fixed diameter of the pulmonary band, as the child grows, pulmonary blood flow will eventually be inadequate and cyanosis will result, necessitating further surgical intervention. Often in infants with unobstructed pulmonary blood flow and single-ventricle anatomy, a concomitant coarctation will need to be repaired at the time of pulmonary artery banding.

To avoid the complications of pulmonary artery banding in the neonate or infant with excessive pulmonary blood flow and single-ventricle physiology, Bradley and colleagues suggested the strategy of pulmonary artery division with placement of a systemic to pulmonary artery shunt; this strategy has yielded excellent clinical results.⁸

Systemic Outflow Obstruction (Subaortic Stenosis)

Some children with single ventricles can present in infancy with systemic ventricular outflow tract obstruction (subaortic stenosis), which may also develop later. The resultant myocardial hypertrophy can adversely affect the eventual suitability for a Fontan procedure. Patients at risk are those in whom the aorta arises above a small outlet chamber, such as in tricuspid atresia or double-inlet left ventricle with a rudimentary right ventricle and transposition of the great arteries, particularly if the ventricular septal defect (sometimes referred to as a bulboventricular foramen) is small or if there is coexisting aortic arch obstruction.⁹ A modified Damus-Kaye-Stansel procedure can be performed to establish unobstructed systemic arterial outflow. This involves transection of both great arteries, anastomosis of the

facing aortic and pulmonary walls, and connection of the distal aorta to the perimeter of the reconstructed proximal great artery. Depending on the pulmonary vascular status, blood flow to the central pulmonary arteries can be reestablished via a systemic to pulmonary shunt, a bidirectional cavopulmonary anastomosis, or the Fontan operation.¹⁰ The Damus-Kaye-Stansel can be performed as a primary procedure¹¹ or after a previous pulmonary artery band.^{7,12,13} Alternatively, a Norwood strategy can be followed in these patients^{14,15} (see [Chapter 128](#)). Some have advocated direct relief of the systemic outflow obstruction by surgical enlargement of the ventricular septal defect (bulboventricular foramen) or resection of subaortic stenosis.^{7,16,17}

Obstructed Pulmonary Venous Return

A particularly unfavorable subset of patients with single ventricles is those with total anomalous pulmonary venous connection.¹⁸⁻²⁰ Even with successful correction of the pulmonary venous return, these patients can have persistent pulmonary artery hypertension, probably related to fetal pulmonary vein and artery abnormalities,²⁰ which precludes the application of the Fontan procedure. To a lesser extent, children with a restrictive atrial communication and an abnormal left atrioventricular valve (as in mitral atresia) are at risk for the development of pulmonary artery hypertension.²¹ Opening of the atrial septum by percutaneous atrial septostomy or stent placement in the catheterization laboratory or surgical atrial septectomy should be performed once this condition has been recognized.

BIDIRECTIONAL CAVOPULMONARY ANASTOMOSIS

The original cavopulmonary shunt was the Glenn procedure (anastomosis of the divided right pulmonary artery to the superior vena cava with ligation of the proximal superior vena cava).²² The advantages of a venous over an arterial shunt in the palliation of cyanotic heart disease are twofold. First, the venous blood that enters the pulmonary artery is much more desaturated, and therefore a higher take-up of oxygen per milliliter of blood is possible. Second, systemic venous return is diverted to the lungs, thus reducing the volume load on the single ventricle. The original Glenn anastomosis fell into disfavor; it could not be used in neonates because of elevated pulmonary vascular resistance.²³ There were also reports of the development of ipsilateral pulmonary arteriovenous malformations.²⁴ However, it was noted that patients with a previous classical Glenn anastomosis fared better with a subsequent Fontan procedure.²⁵ For patients considered high risk for the Fontan procedure, a bidirectional cavopulmonary anastomosis (the divided superior vena cava anastomosed to the pulmonary arteries supplying both lungs) could be used successfully as an alternative to the Fontan or as a staging procedure for the Fontan^{26,27} ([Fig. 129-1](#)). The hemi-Fontan modification of the cavopulmonary shunt involves patch augmentation of the central pulmonary arteries and a connection between the

FIGURE 129-1 ■ Bidirectional cavopulmonary shunt. The superior vena cava is fully mobilized, including the junction with the innominate vein. The azygos vein and small venous branches near the innominate vein junction are ligated to prevent runoff into the inferior vena cava territory. The main and right pulmonary arteries and a right systemic to pulmonary artery shunt, if present, are mobilized. Cardiopulmonary bypass is instituted with venous drainage from a cannula in the right atrial appendage and a further cannula in the superior vena cava near the innominate junction with return via the ascending aorta. The operation is performed on a beating heart with moderate hypothermia (28°C to 32°C), but a period of aortic cross-clamping may be required for correction of other cardiac anomalies. Any right-sided systemic aortopulmonary shunt is occluded and subsequently taken down. The right and main pulmonary arteries are mobilized. The superior vena cava is snugged down. A vascular clamp is applied just above the cavoatrial junction, taking care not to damage the sinus node. The superior vena cava is divided immediately above the clamp, the cardiac end is oversewn, and the clamp is released. The upper margin of the right pulmonary artery is incised. The superior vena cava is anastomosed in an end-to-side manner with the upper margin of the right pulmonary artery. The suture is interrupted in several places to help avoid a purse-string effect and narrowing of the anastomosis. Additional sources of pulmonary blood supply, such as forward flow over a stenosed pulmonary outflow tract or left-sided arterial pulmonary shunt, are usually left in place.

right atrial–superior vena cava junction and pulmonary arteries. Norwood and Jacobs reported improved survival with the Fontan operation in children with hypoplastic left heart syndrome who had undergone an intermediate hemi-Fontan procedure.²⁸ Subsequent studies showed significantly improved outcomes in patients with a Fontan procedure who were staged with a bidirectional cavopulmonary anastomosis compared with those who were not staged.^{21,29} The bidirectional cavopulmonary anastomosis can be performed safely in children younger than 6 months³⁰ and is now routinely performed electively between 4 and 6 months of age, even in children without prior surgical palliation.

Additional Sources of Pulmonary Blood Flow

Whether an additional source of pulmonary blood flow (such as a patent ductus arteriosus, patent right

ventricular outflow tract or a tight pulmonary artery band, or systemic to pulmonary artery shunt) should be eliminated at the time of the cavopulmonary anastomosis remains open to discussion. Comparisons of patients with and without sources of additional pulmonary blood flow after a bidirectional cavopulmonary anastomosis have shown no deleterious effect at the time of the eventual Fontan procedure.³¹⁻³³ Evidence shows that leaving an additional source of pulmonary blood flow after the bidirectional cavopulmonary anastomosis can enhance pulmonary arterial growth.^{32,34} Some patients do not tolerate this increased pulmonary blood flow, which manifests as pleural effusions and superior vena cava syndrome. These patients can be managed by catheter-based techniques to occlude the sources of additional pulmonary blood flow.³⁵

Some have argued that a bidirectional Glenn anastomosis with an additional source of pulmonary blood flow can serve as definitive palliation without a subsequent Fontan procedure, especially in high-risk cases.^{36,37} A multi-institutional paper from Italy reviewed 246 patients with a mean age 4.7 ± 6.2 years (range, 12 months to 30 years) who underwent a bidirectional cavopulmonary anastomosis leaving intact antegrade accessory pulmonary blood flow.³¹ On intermediate follow-up of 4.2 ± 2.8 years, 173 patients (70.3%) did not require a completion Fontan procedure and had a mean resting arterial oxygen saturation of $87\% \pm 4\%$. The actuarial freedom from a Fontan procedure at 7 years was 70.2% for the entire cohort. These results suggest that this strategy provided sustained palliation for selected patients with a single-ventricle circulation and may indicate that the Fontan route is not necessarily the universal palliation for all single-ventricle circulations.

Bilateral Bidirectional Cavopulmonary Anastomoses

Approximately 15% of children with single ventricles undergoing a bidirectional cavopulmonary anastomosis will have a persistent left superior vena cava draining to the coronary sinus.^{38,39} Although an earlier report from the Hospital for Sick Children in Toronto suggested that the presence of a second superior vena cava was a risk factor for thrombosis and failure to progress to the Fontan procedure,³⁹ a report from our institution did not identify any adverse clinical outcomes in patients undergoing bilateral bidirectional cavopulmonary anastomoses compared with those undergoing a unilateral bidirectional cavopulmonary anastomosis.³⁸

Kawashima Operation and Pulmonary Arteriovenous Malformations

Some children with single-ventricle anatomy, particularly those with heterotaxy syndrome, have an interrupted inferior vena cava with azygos continuation to the right superior vena cava or hemiazygos continuation to a persistent left superior vena cava. After initial palliation in infancy, as necessary, with pulmonary artery banding or a systemic to pulmonary artery shunt determined by the status of the pulmonary blood flow, definitive palliation can be accomplished with a Kawashima operation.⁴⁰ This

consists of a bidirectional cavopulmonary anastomosis (bilateral in the case of a persistent left superior vena cava) without the division of the azygos (hemiazzygos) continuation. In effect, this routes all of the systemic venous return except hepatic and mesenteric flow to the pulmonary arteries. A significant percentage of these patients will develop pulmonary arteriovenous malformations (AVMs) in both lungs with resultant cyanosis. This is analogous to the ipsilateral pulmonary AVMs observed with the classical Glenn anastomosis.²⁴ There seems to be some factor in the hepatic venous effluent that, if not circulated to the lung, results in the development of these AVMs.⁴¹ Rerouting the hepatic and mesenteric venous blood flow to the pulmonary arteries by completing the Fontan procedure has been shown to resolve this problem in most patients.⁴²⁻⁴⁴

Glenn Anastomosis versus Hemi-Fontan Procedure

As an intermediate stage to the Fontan procedure, either a bidirectional Glenn anastomosis or a hemi-Fontan procedure can be performed. Although there are advocates for both operations, there are few studies comparing the two operations in similar groups of patients. The hemi-Fontan procedure, as described initially by Norwood and Jacobs,²⁸ involves patch augmentation of the central pulmonary arteries and a connection between the right atrial-superior vena cava junction and pulmonary arteries with elimination of alternative sources of pulmonary blood flow. Although it is a more extensive operation, it simplifies the eventual Fontan procedure, particularly if a lateral tunnel Fontan is planned.⁴⁵ It also has the potential advantage of allowing nonsurgical completion of the Fontan circulation in the cardiac catheterization laboratory,⁴⁶ although this nonoperative Fontan completion can also be used with the bidirectional Glenn anastomosis.⁴⁷ Sinus node dysfunction appears to be more common early after the hemi-Fontan procedure compared with the bidirectional Glenn anastomosis, but this was no longer significant at time of hospital discharge.⁴⁸ Based on magnetic resonance imaging (MRI) reconstructions and computational and experimental fluid dynamics methodologies, it appears that the bidirectional Glenn anastomosis is more energy efficient than the hemi-Fontan procedure.⁴⁹

ONE AND ONE-HALF VENTRICLE REPAIR

In children with a marginal pulmonary ventricle, the standard surgical options are a Fontan procedure or a high-risk biventricular repair, as is commonly seen in patients with pulmonary atresia and intact ventricular septum.⁵⁰ To reduce the risk of biventricular repair and to combat the long-term attrition related to the "Fontan state," Billingsley and colleagues proposed recruiting the hypoplastic pulmonary ventricle to manage part of the systemic venous return by closing the atrial communication, enlarging the right ventricular outflow tract, and adding a cavopulmonary anastomosis so that the small right ventricle is tasked with pumping only the venous

return from the inferior vena cava and not the entire cardiac output.⁵¹ The concept of a one and one-half ventricle repair has since been extended to other abnormalities,⁵²⁻⁵⁴ such as unbalanced atrioventricular septal defects and straddling atrioventricular valves, and as an adjunct to the repair of Ebstein anomaly.⁵⁵ Strict criteria to distinguish which patients would benefit from a one and one-half ventricle repair as opposed to a biventricular repair or a Fontan procedure are not well defined.⁵⁶ Similar physiology can be achieved by only partially closing the atrial communication without performing a cavopulmonary anastomosis. This allows decompression of the smaller right-sided ventricle through this atrial communication with the disadvantage of some systemic arterial desaturation. The advantage of this modification of the one and one-half ventricle repair is that, if the pulmonary ventricle grows sufficiently to handle the complete cardiac output, the atrial communication easily can be closed in the catheterization laboratory at a later date, thus allowing for complete separation of the pulmonary and systemic circulations.

SELECTION CRITERIA FOR THE FONTAN PROCEDURE

The initial selection criteria for the procedure described by Fontan and colleagues for patients with tricuspid atresia, known as the "ten commandments," were stringent (Box 129-1).⁵⁷ With increasing experience, these criteria have been relaxed; however, because of the unique physiology that accompanies the Fontan circulation, proper patient selection remains crucial.

The age of patients undergoing the Fontan operation has been progressively lowered as experience has been gained. Increased pressure and volume load of the single ventricle, such as occurs after systemic to pulmonary artery shunts, is a risk factor for subsequent failure of the Fontan operation; therefore, early ventricular unloading with a bidirectional Glenn anastomosis has been advocated. In short-term studies, regression of ventricular mass was observed in children younger than 3 years who underwent a bidirectional Glenn anastomosis but not in children 10 years or older who underwent the same procedure.⁵⁸ Similarly, younger age at the time of

BOX 129-1

The "Ten Commandments" for Selection of Patients with Tricuspid Atresia for the Fontan Procedure

1. Minimum age 4 years
2. Sinus rhythm
3. Normal caval drainage
4. Right atrium of normal volume
5. Mean pulmonary artery pressure ≤ 15 mm Hg
6. Pulmonary arterial resistance < 4 U/m²
7. Pulmonary artery to aorta diameter ratio ≥ 0.75
8. Normal ventricular functions (ejection fraction > 0.6)
9. Competent left atrioventricular valve
10. No impairing effects of previous shunts

bidirectional Glenn shunt or Fontan operation was also associated with superior exercise performance compared with those in whom surgery was delayed until a later age.⁵⁹ In contrast to Fontan's initial restriction of minimum age older than 4 years, recent data show that for patients with a dominant left ventricle (e.g., tricuspid atresia), with an average follow-up of more than 7.5 years, postoperative exercise capacity, cardiac index, and ventricular ejection fraction were significantly better in children who had their Fontan completion when they were younger than 3 years compared with a group who were older than 3 years.⁶⁰ A multivariable analysis of risk factors after the Fontan operation in 406 patients did not identify young age as a risk factor for unfavorable outcome.⁶¹ Pizarro and colleagues demonstrated in 107 children that Fontan completion can be performed safely in children at a median age of 13 months.⁶² It remains to be seen if a very early Fontan procedure has a better long-term outcome than one performed at a later age, particularly in patients with well-balanced circulations. It is certain that current strategies of early unloading of the single ventricle with an intermediate bidirectional cavopulmonary anastomosis or hemi-Fontan procedure has allowed for successful Fontan completion at a younger age.

Preoperative sinus rhythm is not an absolute requirement for a successful Fontan procedure,^{63,64} although patients without preoperative sinus rhythm are more likely to have heterotaxy syndrome, which is a predictor of post-Fontan rhythm disturbances.^{65,66} The requirement in Fontan's "ten commandments" for normal right atrial volume or normal caval drainage no longer seems to be of concern. On the other hand, unobstructed pulmonary venous drainage is an absolute necessity (see [Obstructed Pulmonary Venous Return](#) section).

The pulmonary vasculature and ventricular function remains the most important selection criteria for successful outcome after the Fontan operation.⁶¹ Pulmonary arteriolar resistance ($<4 \text{ U/m}^2$)⁶⁷ and mean pulmonary artery pressure ($<15 \text{ mm Hg}$) should be low.^{61,66} Assessment of the pulmonary vascular bed can be difficult, in particular in the presence of accessory sources of pulmonary blood flow such as aortopulmonary collateral vessels or surgical shunts.

Small size of the central pulmonary arteries has been considered a predictor of poor outcome after the Fontan procedure (death or takedown). Various attempts have been made to standardize these measurements. The McGoon ratio, originally used in patients with pulmonary atresia and ventricular septal defect,⁶⁸ is obtained from the sum of the diameters of the immediately prebranching portion of the left and right pulmonary arteries divided by the diameter of the descending aorta just above the diaphragm. In a retrospective study, Fontan and colleagues⁶⁹ found that the risk of early death or Fontan takedown rose sharply when the McGoon ratio was less than 1.8. The Nakata pulmonary artery index⁷⁰ is derived from the sum of the diameter of the left and right pulmonary arteries (measured just before the origin of the upper lobe branches) divided by the body surface area. Patients with unfavorable outcome after a modified Fontan for tricuspid atresia were shown to have a lower

pulmonary artery index than those with good results (185 ± 47 versus $276 \pm 83 \text{ mm}^2/\text{m}^2$),⁷¹ but this was not confirmed by others.^{72,73} The usefulness of these indices has been questioned because they do not take into account the compliance and maturity of the pulmonary vascular system, the peripheral and intraparenchymal pulmonary arteries, or any distortion of the central pulmonary arteries that may have occurred because of previous shunts or bands. Furthermore, many of these studies implicating small pulmonary artery size as a risk factor for poor Fontan outcomes were performed before current strategies of earlier staged Fontans using total cavopulmonary connections.⁷²

Adequate ventricular function remains a prime determinant for a successful Fontan circulation.⁶¹ The incidence of common causes of impaired systemic ventricular performance seen in the past can be reduced. For example, early elimination of volume overload by an intermediate bidirectional cavopulmonary connection or hemi-Fontan procedure can preserve ventricular function.^{45,74} Also, aggressive treatment of systemic ventricular outflow obstruction (see [Systemic Outflow Obstruction](#) section) can reduce deleterious ventricular hypertrophy in these patients with resultant improved ventricular function at the time of the Fontan procedure. Also, some feel that the presence of systemic to pulmonary collateral artery connections can increase the volume load of the single ventricle with resultant impaired ventricular function or increased workload on the heart.⁷⁵⁻⁷⁸ The impact of these collaterals can be reduced in the cardiac catheterization laboratory by coil occlusion, although some groups question its usefulness.⁷⁹⁻⁸²

Atrioventricular valve insufficiency remains a risk factor for the Fontan procedure,⁸³ particularly in children with heterotaxy syndrome.^{18,66} Because this can cause volume overload of the single ventricle with the potential for impaired ventricular function, it is important to address this surgically when possible. Repair of the incompetent systemic atrioventricular valve can be performed reliably at the time of the bidirectional cavopulmonary anastomosis or at the time of the Fontan.⁸⁴⁻⁸⁶ If necessary, atrioventricular valve replacement is an option.⁸⁷

SURGICAL EVOLUTION OF THE FONTAN PROCEDURE

The Fontan procedure was first applied in 1968 for tricuspid atresia based on the principle that the right atrium could be used as a pumping chamber for the pulmonary circulation.⁸⁸ The original description of the atriopulmonary connection included the insertion of an aortic or pulmonary homograft valve at both the inflow and the outflow of the right atrium as well as a classical Glenn anastomosis of the superior vena cava to the right pulmonary artery. Kreutzer and colleagues described the use of the patient's native pulmonary valve between the right atrium and pulmonary artery.⁸⁹ Bjork and coworkers were worried about the long-term durability of conduits and valve prostheses and devised a valveless atrioventricular anastomosis whereby the right atrial appendix is

FIGURE 129-2 ■ Lateral tunnel Fontan. The beginning of the operation may involve performing a bidirectional cavopulmonary anastomosis (see Fig. 129-1), or this may already be in place. For cardiopulmonary bypass, a venous cannula is placed low down on the inferior vena cava and a further cannula high up in the superior vena cava near the junction with the innominate vein. The ascending aorta is cannulated. The operation is performed using moderate hypothermia. Any existing systemic to pulmonary artery shunts are taken down. The aorta is cross-clamped, and cold blood cardioplegia is infused. A needle vent is placed in the ascending aorta. The main pulmonary artery is transected. To prevent bleeding or aneurysm formation after closure of the proximal pulmonary artery stump, the suture line is reinforced with two small Teflon felt strips and the pulmonary valve leaflets are included in the suture line. The distal main pulmonary artery is closed, taking care not to distort or narrow the branch pulmonary arteries. **A**, The right atrium is opened along the crest of the septum. The atrial septal defect is enlarged if necessary, and the size of the intra-atrial baffle is measured between the eustachian valve (EV) and crista terminalis (CT). **B**, Future site of baffle between the superior vena cava and inferior vena cava. **C**, A Gore-Tex tube of at least 16-mm diameter is cut to size and opened longitudinally, and if required, a 4- to 5-mm fenestration is cut. **D** and **E**, The prosthetic baffle is sewn halfway around the junction of the inferior vena cava with the right atrium, along the posterior wall of the atrial septum, along the CT, and halfway around the junction with the superior vena cava. Care is taken to avoid injury to the sinus node. **F**, The cardiac end of the transected superior vena cava is anastomosed in an end-to-side manner with the undersurface of the right pulmonary artery.

anastomosed to the right ventricle with the aid of an autologous pericardial patch.⁹⁰ It soon became apparent that neither valves nor the rudimentary right ventricle needed to be incorporated into the Fontan connection, so the Fontan procedure evolved into a direct atriopulmonary connection with closure of the atrial communication for tricuspid atresia.

Lateral Tunnel Fontan (Total Cavopulmonary Connection)

Studies in hydrodynamic models by de Leval and colleagues revealed that the atriopulmonary connection performed poorly in terms of flow energetics because of turbulence that was further exaggerated by pulsation.⁹¹ In contrast, a cavopulmonary connection had mainly laminar flow patterns. In this design, the superior vena cava blood drains directly into the pulmonary artery, and inferior vena cava blood is baffled through a straight intra-atrial

conduit to the pulmonary artery (Fig. 129-2). Additional theoretical advantages are a reduced risk of thrombosis because of less blood stasis and exposure of only a limited portion of the right atrium to high venous pressures, thus reducing the risk of arrhythmias. In addition, because the coronary sinus remains in the lower pressure pulmonary venous atrium, myocardial venous drainage is unobstructed. This introduction of total cavopulmonary connection, coupled with an intermediate stage of a bidirectional Glenn anastomosis²⁶ or a hemi-Fontan procedure,²⁸ greatly improved clinical results with the Fontan procedure.⁷⁴

Fontan Fenestration

Another important clinical improvement was the creation of a fenestration in the Fontan baffle,⁹² which allows systemic venous blood to shunt to the pulmonary venous atrium, achieving better preload for the systemic

FIGURE 129-3 ■ Construction of extracardiac Fontan on cardiopulmonary bypass. Cannulation for cardiopulmonary bypass is as described for the lateral tunnel Fontan operation (see Fig. 129-2). It is particularly important that the inferior vena cava is cannulated low down. Any systemic to pulmonary artery shunts are taken down. Transection and closure of the main pulmonary artery can be facilitated by a short period of cardioplegic arrest. A needle vent is placed in the ascending aorta. The space between the right lower pulmonary vein and the inferior vena cava is dissected. The cannula in the inferior vena cava is snared, and a clamp is placed across the cavoatrial junction, taking care to avoid occluding the coronary sinus. **A**, The cavopulmonary junction is transected on the clamp, and the cardiac end is oversewn. A Gore-Tex tube of at least 16-mm diameter (22-mm diameter in adults) is anastomosed in an end-to-end manner to the transected inferior vena cava. The conduit is gently curved around the atrium toward the right pulmonary artery. The cavopulmonary shunt is temporarily occluded, and the inferior surface of the right pulmonary artery is incised. The top end of the prosthesis is anastomosed in an end-to-side manner to the pulmonary artery. If a fenestration is required, a side-biting clamp is placed on the free wall of the right atrium and a further clamp opposite on the prosthesis. A 5-mm fenestration is cut in the prosthesis, and a slightly larger hole is cut in the opposite right atrial wall. **B**, To avoid obstruction of the fenestration by atrial tissue, the anastomotic suture line is placed a few millimeters away from the hole in the prosthesis.

ventricle at the cost of some systemic arterial desaturation. Thus, cardiac output is maintained and systemic venous pressure is reduced. The fenestration can be closed later by a transcatheter approach. A retrospective study by Bridges and associates showed a significant decrease in pleural effusions and hospital stay compared with nonfenestrated patients.⁹³ Consequently, the fenestrated Fontan circuit has become the procedure of choice for the high-risk population.

Baffle fenestration remains controversial in standard-risk patients, with a number of retrospective studies showing no benefit from fenestration,^{61,94,95} whereas other studies showed a decreased rate of Fontan failure and lower incidence of significant pleural effusions.⁹⁶ A prospective randomized trial by Lemler and colleagues showed improved clinical outcome with less pleural drainage, shorter hospital stay, and less need for additional postoperative procedures in patients with a fenestration.⁹⁷ Fontan fenestration has also been shown to have a beneficial effect on late outcome.⁹⁸

Apart from those patients in whom low saturations are a clinical indication for closure of the fenestration, it is not known whether fenestrations should be closed and,

if so, when. A quarter or more of fenestrations will close spontaneously.⁹⁶ The remainder can be relatively easily occluded by catheter intervention. A follow-up of patients with a mean of 3.4 years following device closure showed improved oxygen saturation with an average increase of 9.4%, reduced need for anticongestive treatment, and improved somatic growth. However, 12% of patients developed new arrhythmias.⁹⁹

Lateral Tunnel versus Extracardiac Conduit

Another modification in the design of the Fontan pathway involves the use of an extracardiac interposition graft between the transected inferior vena cava and pulmonary artery (Fig. 129-3).¹⁰⁰ The extracardiac conduit initially was designed to avoid pulmonary and systemic venous obstruction in patients with a small atrium. Its use has the additional advantage that it avoids extensive atrial suture lines that are potentially arrhythmogenic. Thrombogenicity and lack of growth of the prosthetic conduit remain potential late problems.

The hemodynamic superiority of cavopulmonary connections with total right heart bypass over atriopulmonary connections is generally accepted, and most surgeons now create some form of cavopulmonary connection with complete exclusion of the right heart. The lateral tunnel Fontan optimizes flow dynamics in the pulmonary artery, leaves the coronary sinus in the low pressure atrium, and has a low risk of damage to the atrioventricular node. The same advantages can be attributed to the extracardiac Fontan procedure. Computational flow dynamics show no significant differences in energetics or geometry between the two types of cavopulmonary connections, with the cross-sectional area of the pulmonary arteries having a far more significant impact on hemodynamics than the type of Fontan connection.^{101,102} The extracardiac Fontan procedure has the additional advantage that no intra-atrial access is required and thus can be done without aortic cross-clamping and, in suitable cases, also without the use of cardiopulmonary bypass.¹⁰³⁻¹⁰⁶

A theoretical advantage of the extracardiac Fontan operation over the lateral tunnel Fontan is thought to be the absence of arrhythmogenic suture lines, but bradyarrhythmias have been observed with the extracardiac Fontan.¹⁰⁷ Although some reports have shown more postoperative arrhythmias with the lateral tunnel Fontan,^{108,109} other studies have shown no difference in postoperative arrhythmias comparing the two surgical techniques.^{48,110,111} One study from the Medical University of South Carolina found an increased incidence of sinus node dysfunction in a contemporaneous extracardiac group.¹¹²

Drawbacks of the extracardiac Fontan operation include the thrombogenicity of the prosthetic conduit and lack of conduit growth, in particular with the current tendency for surgery in small children. At the age of 2 to 4 years and body weight of 12 to 15 kg, the inferior vena cava diameter and inferior vena cava to pulmonary artery distance are approximately 60% to 80% of adult values. Oversizing the conduit may be tempting, but this has been shown to result in unfavorable Fontan hemodynamics and conduit thrombosis.¹¹³ Intermediate follow-up of about 3 years of children with an extracardiac Fontan has shown an average reduction in conduit cross-sectional area of 14%.¹¹⁴ Clearly, these extracardiac conduits need careful observation over time.

Nonoperative Fontan

The concept of completing the Fontan procedure in the cardiac catheterization laboratory was introduced with promising results from studies with laboratory animals¹¹⁵ and children.^{46,47} This technique requires modification of the operative technique for the bidirectional Glenn anastomosis or the hemi-Fontan procedure to allow for the percutaneous seating of a covered stent as an intra-atrial conduit. Although this procedure currently uses experimental stents and innovative techniques, it is promising and bears careful study and follow-up.

Fontan for Biventricular Hearts

Certain cardiac defects with two well-formed ventricles are better served with a Fontan procedure than with a

high-risk biventricular repair. A typical group of patients have double-outlet right ventricle with a remote ventricular septal defect or a straddling atrioventricular valve, which would make a biventricular repair problematic. Results with the Fontan procedure in these patients are good.^{67,116,117} Other anatomic substrates in which the Fontan procedure might be more desirable than a biventricular repair are congenitally corrected transposition of the great arteries (with difficult anatomy for a double-switch procedure) or unbalanced atrioventricular septal defects.

OUTCOME AFTER THE FONTAN PROCEDURE

Early Mortality and Morbidity

Approximately 40 years after the introduction of the Fontan operation, the early mortality after the Fontan procedure, which historically was in excess of 20%,¹¹⁸ has steadily come down to less than 5%.^{112,119-122} This is in spite of liberalizing the original patient selection criteria and extending the procedure to many forms of complex single ventricle. Multiple factors have contributed to this improved early outcome. Certainly, volume unloading of the single ventricle by an early bidirectional cavopulmonary anastomosis or a hemi-Fontan procedure has markedly improved the suitability for a subsequent Fontan operation,^{21,28,29,74} although some physicians argue that staging with an intermediate bidirectional cavopulmonary anastomosis is unnecessary.⁹⁵ The introduction of the total cavopulmonary connection with its more energy-efficient circulation, with the use of either a lateral tunnel⁹¹ or an extracardiac conduit,¹²³ has clearly been a huge advance in the improved outcome of the Fontan operation. Other factors potentially responsible for the improvement in the early results with the Fontan operation (identified by some but disputed by others) are the use of an atrial fenestration^{61,94,96,97} and preoperative occlusion of aortopulmonary collaterals.^{75,78,81}

Patients with a single ventricle and heterotaxy syndrome always have been a particularly high-risk population for the Fontan procedure because of multiple associated cardiovascular abnormalities, including variable anatomy of the sinus node and conduction system, potential for pulmonary venous obstruction, and atrioventricular valve regurgitation. Some reports have shown improved outcomes with these patients after the Fontan procedure, although early mortality and the incidence of postoperative rhythm disturbances and atrioventricular valve regurgitation are higher in the heterotaxy patients compared with the nonheterotaxy patients.^{18,63,65,66}

Pleural and pericardial effusions constitute the most common early morbidity after the Fontan operation. Prolonged chest tube drainage has been associated with longer cardiopulmonary bypass times.^{109,121} It is interesting to note that effusions are reduced in patients having Fontan completion without cardiopulmonary bypass¹⁰³ or nonoperative Fontan completion by catheter techniques.⁴⁷ The use of a baffle fenestration has been reported

to reduce the duration of postoperative chest tube drainage.^{96,97}

Sinus node dysfunction and atrial arrhythmias occur frequently after the Fontan procedure, particularly in patients with heterotaxy syndrome.¹⁸ It has been proposed that an extracardiac conduit will result in fewer atrial arrhythmias compared with a lateral tunnel Fontan procedure. Although some authors have found this to be true,^{108,109} others have found no difference in arrhythmias comparing the two techniques,^{110,111} and there is even one report of a higher incidence of sinus node dysfunction with the extracardiac Fontan.¹¹²

The incidence of early Fontan takedown is generally 1% to 3% in many series and is thought to be related to improper patient selection or to unrecognized or unrecognized anatomic problems, such as outflow tract obstruction or pulmonary or systemic venous pathway obstruction.^{61,98,119,122} Although Fontan takedown has a high mortality, some of these patients can be candidates for a subsequent successful Fontan after correction of underlying treatable abnormalities.¹²⁴

An uncommon but serious complication after the Fontan procedure is hemidiaphragmatic paralysis as a result of phrenic nerve injury. Patients with a paralyzed hemidiaphragm have longer hospital stays and a higher incidence of prolonged pleural effusions and ascites.^{125,126} There is evidence that subdiaphragmatic venous hemodynamics are abnormal, even after diaphragm plication.¹²⁷

Late Outcomes

With improving operative survival, late outcome after the Fontan operation is becoming increasingly important. In 1990, 2 decades after the introduction of the procedure, Fontan reported that the “Fontan state” was associated with a premature decline in functional status and survival.¹¹⁸ Even when atriopulmonary and atrioventricular Fontan procedures were performed under perfect conditions, there was a gradual attrition with a predicted survival of 86%, 81%, and 73% at 5, 10, and 15 years, respectively, after the operation. More current series with follow-up of patients undergoing total cavopulmonary connection show overall actuarial survival of 91% at 10 years with the lateral tunnel Fontan¹²² and 93.6% at 10 years¹²⁸ and 85% at 15 years¹²⁹ with the extracardiac Fontan. A study from Children’s Hospital Boston showed that for operative survivors, there was no difference in freedom from death or transplantation after 20 years between patients with an atriopulmonary connection and those with a total cavopulmonary connection.¹³⁰

In addition to ongoing late mortality with the Fontan operation, these survivors have impairment of exercise function. In a large multicenter study examining 546 patients, despite a normal ejection fraction in 73% of patients, only 28% had a normal diastolic grade.⁷⁴ Peak oxygen consumption on exercise was only 65% of normal for age; this finding has been corroborated by others.^{131,132} It is worrisome that age-adjusted exercise capacity tended to worsen with age.^{74,133}

The exact reasons for the late attrition after the Fontan operation are unknown but no doubt are complex and multifactorial. Serial angiographic measurement of

pulmonary artery size in Fontan patients shows that pulmonary artery growth lags behind somatic growth¹³⁴ or even fails to grow at all, resulting in a decreasing pulmonary artery index with time.¹³⁵ A correlation can be made between low pulmonary artery index and length of follow-up as well as with an unfavorable outcome.¹³⁵

Atrial Arrhythmias

With the widespread adoption of the total cavopulmonary connection (either lateral tunnel or extracardiac Fontan) rather than atriopulmonary connections, the incidence of late atrial arrhythmias and the need for pacemakers have greatly diminished.^{122,128} Patients with the older atriopulmonary connection are more prone to significant atrial arrhythmias (see [Fontan Conversion](#) section for a discussion on management of these patients). Children with heterotaxy syndrome remain at risk for late arrhythmias after the Fontan operation, even with the newer total cavopulmonary connection techniques.^{18,65,66}

Venovenous Collaterals

After the Fontan operation, significant venovenous collateral channels can develop, which result in significant right-to-left shunting with resultant hypoxemia and cyanosis. These abnormal venous channels can be between the systemic veins and the pulmonary veins or pulmonary venous atrium. Once recognized, they can usually be interrupted by interventional catheterization techniques and less commonly require surgical intervention.^{136,137} In patients with progressive cyanosis after the Fontan operation, an aggressive search for collateral vessels should be made using cardiac catheterization and angiography followed by interruption of significant collateral channels.

Thromboembolism and Prophylactic Anticoagulation

Thromboembolic complications occur both early and late after the Fontan procedure. The true incidence of thromboembolism is not known, but various studies have shown an incidence of “silent” intracardiac thrombus ranging from 9% to 33%,^{107,138-140} with a higher rate found when transesophageal echocardiography is used. Cerebrovascular events, including thromboembolic strokes, occur in 2% to 9% of Fontan patients.^{141,142} The presence of a fenestration may increase this risk,¹⁴² whereas the use of aspirin may ameliorate it.¹⁴¹ Many factors contribute to the risk for thrombus formation, including suboptimal flow patterns, arrhythmias, cyanosis, presence of foreign material in the circulation, pre-existent coagulopathies, and liver dysfunction.

Information on the prevention of thromboembolic complications after the Fontan procedure is inconsistent. Some centers recommend aspirin alone as prophylaxis,^{143,144} whereas others recommend anticoagulation with warfarin.^{140,145} It is well known that anticoagulant therapy is not without risk. Anticoagulant-related bleeding is a cause for concern, particularly in active children. In the presence of cyanosis or heart failure, anticoagulation control can be difficult. Reviews of the

need for and type of anticoagulation after the Fontan operation have emphasized the lack of a uniform consensus and have underscored the need for prospective clinical studies.¹⁴⁶⁻¹⁴⁸

Protein-Losing Enteropathy

Protein-losing enteropathy is a relatively rare but debilitating complication with a reported incidence of up to 15%. The condition involves the loss of protein within the gastrointestinal tract and can occur from weeks to years after the Fontan operation, with 50% mortality at 5 years following diagnosis.¹⁴⁹ The precise reasons for its occurrence are not known, but it has been suggested that it may be related to abnormal mesenteric blood flow.¹⁵⁰ Clinical manifestations are related to the degree of hypoproteinemia; the nonselective loss of proteins can result in peripheral edema, ascites and effusions, immunodeficiency, and coagulopathy. A detailed investigation of the cardiovascular system should take place and hemodynamics optimized if possible. Symptomatic treatment is with diuretics, diet supplements, and intermittent albumin infusions. Steroids¹⁵¹ and heparin therapy¹⁵² have been shown to improve symptoms and to reduce protein loss in some patients. It is postulated that they act through stabilizing the intestinal mucosal membrane, thus reducing the protein leak. Other treatment modalities that have shown some success are sildenafil use,¹⁵³ atrial pacing,¹⁵⁴ and creation of a surgical fenestration.¹⁵⁵ Ultimately, patients with protein-losing enteropathy may require cardiac transplantation with expected resolution of the enteropathy.¹⁵⁶

Plastic Bronchitis

Plastic bronchitis is another poorly understood and unusual complication after the Fontan procedure. Non-inflammatory mucin-containing casts are formed in the trachea and bronchus. Symptomatic treatment is by bronchoscopic clearance. Small series and case reports have advocated different treatment options, including Fontan baffle fenestration,¹⁵⁷ thoracic duct ligation,¹⁵⁸ and aerosolized tissue plasminogen activator.^{159,160}

MANAGEMENT OF THE FAILING FONTAN

Even with current improvements in surgical strategies for management of children with a single ventricle, there continues to be a seemingly irreducible incidence of late failure, defined as Fontan takedown, need for transplantation, or death.^{29,119,120} Preservation of ventricular function is of paramount importance for successful long-term outcome in patients with univentricular hearts.⁶¹ Methods to preserve ventricular function include volume unloading of the heart with a bidirectional cavopulmonary anastomosis at an early age,²⁹ aggressive relief of systemic ventricular outflow tract obstruction to prevent myocardial hypertrophy and diastolic noncompliance, and repair of atrioventricular valve regurgitation. Although not universally accepted, elimination of systemic to pulmonary

collateral blood flow can help preserve ventricular function as well.⁷⁵ Sometimes dysfunction of the Fontan circulation may be related to atrial arrhythmias or conduction abnormalities, which may respond to conventional pacing techniques^{161,162} or resynchronization pacing.¹⁶³

Fontan Conversion

Conversion of the failing classical atriopulmonary Fontan with refractory arrhythmias to a total cavopulmonary connection with concomitant arrhythmia surgery and correction of hemodynamically significant lesions was introduced by Mavroudis and colleagues in 1998.¹⁶⁴ The operation consists of defined cryoablation lesion sets in the atrium, repair of residual defects such as atrioventricular valve regurgitation, conversion to an extracardiac Fontan connection, and pacemaker placement. An update of their Fontan conversion series in 111 patients¹⁶⁵ reported 1 early death, 6 late deaths, and 6 subsequent transplants, with good rhythm control in over 85% of patients. Other centers have reported similarly good results with this challenging group of patients with low mortality rates and good rhythm control.^{100,166} Conversion to a total cavopulmonary connection with either a lateral tunnel approach or an extracardiac conduit appear equally efficacious.^{167,168}

Heart Transplantation

For patients with a failing Fontan in whom heart failure is the dominant feature or with protein-losing enteropathy refractory to more conventional therapies, cardiac transplantation offers the only solution. Although some series have reported early mortality with transplantation in patients with Fontan procedures in excess of 50%,^{169,170} others have reported 1-year survival rates ranging from 71% to 86%.^{15,156,171,172} Importantly, hospital survivors show uniform resolution of protein-losing enteropathy after transplantation.^{156,171} Of course, there is an incidence of death on the waiting list before heart transplantation¹⁵⁶ as well as the need for chronic immunosuppression and concerns for post-transplant infection, rejection, and late graft failure.

Mechanical Circulatory Support

Mechanical support of the failing Fontan is problematic because of the single functional ventricle. Case reports have described the use of the Berlin Heart as a successful bridge to transplant as a left ventricular assist device (systemic ventricular apical cannulation for pump inflow with ascending aortic cannulation for pump outflow)¹⁷³ and as a "right ventricular" assist device (Fontan systemic venous pathway cannulation for pump inflow with pulmonary artery cannulation for pump outflow).¹⁷⁴ Designs for indwelling axial flow pumps for support of the failing Fontan circulation as a bridge to recovery or as a bridge to transplant have also been tested.^{175,176} Because of the ongoing shortage of suitable donor hearts for transplantation and the seemingly inevitable incidence of Fontan failure with time, it is hoped that mechanical devices will be designed and tested in the future to successfully

FIGURE 129-4 ■ A completed Y-graft Fontan is shown, emphasizing the importance of anastomosing the right and left limbs of the Y-graft away from the Glenn anastomosis. The fenestration to the right atrium is also depicted.

support the patient with a failing Fontan circulation indefinitely, without the need for transplantation.

COMPUTER MODELING TO OPTIMIZE FONTAN ENERGETICS

Computational fluid dynamics¹⁷⁷ have demonstrated designs of the total cavopulmonary connection that can cause flow disturbances and energy dissipation. Optimizing flow and diminishing power loss in the Fontan circuit presumably can improve hemodynamic efficiency and potentially improve long-term outcomes. In vitro and computational fluid dynamics studies have shown reduced energy losses with caval offset¹⁷⁸ and with flaring of the cavopulmonary anastomosis,¹⁷⁹ thus prompting modification of the total cavopulmonary connection surgical procedure.

Using computational fluid dynamics, an optimized total cavopulmonary connection using a bifurcated Y-graft for the superior vena cava to pulmonary artery connection and another bifurcated Y-graft for the inferior vena cava to pulmonary artery connection was proposed¹⁸⁰ (U.S. Patent No. 7811244). Although this “Optiflo” connection had superior flow characteristics predicted by

flow modeling, the optimized design from a surgical standpoint was cumbersome. Subsequent studies developing surgical designs to balance hepatic blood flow distribution to the right and left pulmonary arteries in children with acquired pulmonary AVMs showed favorable results with a bifurcated Y-graft connection from the inferior vena cava to the branch pulmonary arteries.¹⁸¹ Comparison of the Y-graft Fontan connection with more conventional Fontan connections using computational fluid dynamics have demonstrated improved flow characteristics, reduced energy losses, and balanced hepatic flow distribution to the pulmonary arteries.^{182,183} Based on these improvements in flow dynamics predicted by computerized modeling, the Y-graft Fontan concept has been used clinically¹⁸⁴⁻¹⁸⁷ (Fig. 129-4).

A novel computer-based surgical planning framework that enables one to virtually perform multiple surgical scenarios and determine the one that will yield the best hemodynamic performance before even entering the operating room has been proposed.¹⁸⁸ Such a surgical planning platform offers a unique solution for cases in which hemodynamics (and in particular hepatic flow distribution) are vital to the operation but in which the small patient population and large number of anatomic variations pose a severe obstacle to the establishment of surgical guidelines from clinical studies alone.

Echocardiography

Cardiac Catheterization

Magnetic Resonance Imaging

NATURAL HISTORY**MANAGEMENT**

Neonates and Infants

Indications for Operation

Children and Adults

Indications for Operation

Operative Management

POSTOPERATIVE CARE**OUTCOMES****HISTORICAL ASPECTS**

In an 1866 report titled “Concerning a very rare case of insufficiency of the tricuspid valve caused by a congenital malformation,” Dr. Wilhelm Ebstein (1836-1912), a German physician, described the unusual cardiac findings of a 19-year-old laborer who died of cyanotic heart disease. He accurately described the characteristic anatomic and hemodynamic abnormalities of Ebstein malformation¹ (Fig. 130-1). By 1950, only three case reports of Ebstein malformation had been published.

PATHOLOGIC ANATOMY

Ebstein malformation of the tricuspid valve (TV) is characterized by² (Fig. 130-2):

1. Failure of delamination of the septal, inferior, and anterior leaflets of the TV with subsequent adherence of the leaflets to the underlying myocardium
2. Apical displacement of the functional TV annulus (septal>inferior>anterior)
3. Dilation of the atrialized portion of the right ventricle (RV)

4. Anterior leaflet fenestrations, redundancy or tethering
5. Dilation of the true anatomic TV annulus³

Tricuspid Valve

There is a highly variable TV morphology; the valve is almost always incompetent, and rarely stenotic. The anterior leaflet is usually large and is attached to the annulus; however, it may contain several fenestrations⁴ (Fig. 130-3) and have various points of incomplete delamination. The chordae tendineae may be short and poorly formed.

The inferior and septal leaflet development is variable and most often rudimentary and may even be absent due to failure of the delamination process. The leading edges may be freely mobile with chordal or papillary muscular support, or they may be tethered (adherent) to the endocardium (linear attachment). The point of maximal displacement is at the commissure between the inferior and septal leaflets. In normal hearts, the downward displacement of the septal and posterior leaflets in relation to the anterior mitral valve leaflet is less than 8 mm/m² body surface area. The spectrum of abnormality in Ebstein

malformation can range from only minimal displacement of the septal and inferior leaflets to an imperforate membrane or muscular shelf between the inlet and trabecular zones of the RV. The range of variability is infinite, and the most important pathologic finding is “failure of delamination” of the leaflets. There often is marked dilation of the true TV annulus, which is not displaced, and a large chamber separating the true annulus from the functional RV is the “atrialized” portion of the RV (aRV).

Right Ventricle

The RV is divided into two regions: the area involved with the malformation (i.e., the inlet portion or the aRV)

that is functionally integrated with the right atrium (RA), and the area that is not involved by the malformation and consists of the other two components of the RV—the trabecular and outlet portions, which constitute the functional RV. The “atrialized” portion of the RV can become disproportionately dilated and may account for more than half of the RV volume. The majority ($>2/3$) of hearts with Ebstein malformation have RV dilation. Dilation often involves not only the atrialized inlet portion of the RV but also the functional RV apex and outflow tract. In some cases, RV dilation is so marked that the ventricular septum is deviated leftward, compressing the left ventricular (LV) chamber. In such cases, the short-axis view demonstrates a circular RV and a D-shaped LV.

FIGURE 130-1 ■ Figure from the original Ebstein anomaly case report. The right atrium and right ventricle are shown opened along the right border beginning at the superior vena cava. A, Right atrium; B, right ventricle; C, rudimentary septal leaflet of tricuspid valve with its chordae tendineae, which insert on the endocardium of the ventricular septum; D, opening through which one can get into the right conus arteriosus, and in the opposite direction, one can get into the sac that is formed by membrane; E, fenestrations seen in the tricuspid leaflets. (From Said SM, Dearani JA: Ebstein anomaly, congenital tricuspid valve regurgitation and dysplasia. In Allen HD, Driscolle DJ, Shaddy RE, Feltes TF, editors: *Moss and Adams' heart disease in infants, children, and adolescents*, ed 8, Philadelphia, 2013, Lippincott Williams & Wilkins, Figure 39-1.)

FIGURE 130-2 ■ Severe Ebstein malformation of tricuspid valve (four-chamber view) showing marked downward displacement of shelflike posterior leaflet with attachment to underlying free wall by numerous muscular stumps (arrows), markedly dilated atrialized portion of right ventricle (ARV), small functional portion of right ventricle (RV), leftward bowing of ventricular septum, and marked dilation of right atrium (RA). LA, Left atrium; LV, left ventricle. (From Said SM, Dearani JA: Ebstein anomaly, congenital tricuspid valve regurgitation and dysplasia. In Allen HD, Driscolle DJ, Shaddy RE, Feltes TF, editors: *Moss and Adams' heart disease in infants, children, and adolescents*, ed 8, Philadelphia, 2013, Lippincott Williams & Wilkins, Figure 39-5.)

FIGURE 130-3 ■ A and B, Ebstein heart: marked fenestrations and tethering of the tricuspid valve anterior leaflet. (From Said SM, Dearani JA: Ebstein anomaly, congenital tricuspid valve regurgitation and dysplasia. Associated Cardiac Defects

The most common associated cardiac defects include^{5,6}:

- Atrial septal defect (ASD): either patent foramen ovale or an ASD, mostly secundum, is present in 80% to 94% of the patients
- Ventricular septal defect with or without pulmonary atresia
- RV outflow tract obstruction: this can occur secondary to structural abnormalities (pulmonary valve stenosis or pulmonary atresia), branch pulmonary artery stenosis, and rarely the displaced TV
- Patent ductus arteriosus
- Coarctation of the aorta
- Accessory conduction pathways (Wolff-Parkinson-White [WPW] syndrome) are present in up to 15% to 20% of patients and may predispose patients to arrhythmias. The majority of these pathways are located around the orifice of the malformed TV.
- Left-sided lesions (uncommon)
 - Mitral valve prolapse
 - Accessory mitral valve tissue
 - Subaortic stenosis
 - Bicuspid or atretic aortic valve
 - Muscle bands in the LV cavity
 - Myocardial changes resembling LV non-compaction⁷
- Congenitally corrected transposition of the great arteries (cc-TGA): In patients with cc-TGA, an abnormal systemic atrioventricular valve (morphologic TV) that fulfills the criteria of Ebstein valve is present in 15% to 50% of cases. This Ebsteinoid displacement of the TV into the morphologic RV is different from the classic right-sided Ebstein malformation in that there is usually lack of atrialization of the RV free wall.⁸

CLASSIFICATIONS OF EBSTEIN MALFORMATION

Several classifications have been proposed for Ebstein malformation. In general, classification systems of Ebstein

malformation are difficult since there are infinite variations in the anatomy and no two hearts are alike.

Carpentier in 1988 proposed the following⁹:

Type A: the volume of the true RV is adequate

Type B: a large atrialized component of the RV exists, but the anterior leaflet of the TV moves freely

Type C: severe restriction of the anterior leaflet movement that can cause significant RV outflow tract obstruction

Type D: near complete atrialization of the ventricle except for a small infundibular component

Another classification proposed four types of Ebstein malformation based on valve analysis during surgery.¹⁰

This is our preferred approach, which is to describe the exact anatomy of each of the involved structures of the heart as visualized at the time of surgery (Table 130-1).

This includes comment about the extent of failure of delamination of each leaflet, status of the leading edges of the leaflets, degree of displacement of the septal leaflet, description of the aRV, and size of the RA and RV.

GENETIC FACTORS

Genetic factors in Ebstein malformation are heterogeneous. Most cases are sporadic and familial Ebstein is rare. Rare cases of cardiac transcription factor NKX2.5 mutations, 10p13-p14 deletion, and 1p34.3-p36.11 deletion have been described in association with Ebstein malformation.^{11,12} The results of a mutational analysis in a cohort of 141 unrelated probands with Ebstein malformation has been reported;¹³ eight were found to have a mutation in the gene *MYH7*, and six of the eight patients also had LV noncompaction. This result may warrant genetic testing and family evaluation in this subset of patients.

PATHOPHYSIOLOGY

The functional impairment of the RV and the incompetence of the deformed TV retard forward flow of blood through the right side of the heart into the lungs.

TABLE 130-1 Types of Ebstein Valve Based on the Anatomic Findings during Surgery

Type	Anterior Leaflet		Posterior Leaflet	Septal Leaflet	Atrialized RV Chamber Size
	Size	Mobility			
I	Larger	Mobile	Apically displaced, dysplastic, or absent		Varies from relatively small to large
II	Relatively small and displaced in a spiral fashion toward the apex		Displaced, dysplastic, and usually not reconstructible		Moderately large
III					
IV	Severely deformed; displaced into the RVOT; few or no chordae; direct insertion of the papillary muscles into the leading edge of the valve is common		Typically dysplastic or absent	Represented by a ridge of fibrous material descending apically from the membranous septum	Nearly the entire RV cavity is atrialized; TV tissue is displaced into the RVOT and may cause obstruction of blood flow (functional tricuspid stenosis)

RV, Right ventricle; RVOT, right ventricular outflow tract; TV, tricuspid valve.

Moreover, during contraction of the atrium, the atrialized portion of the RV (which is adjacent to and in continuity with the RA) balloons out (if very thin) or acts as a passive reservoir, thus decreasing the volume to be ejected. During ventricular systole, the atrialized RV contracts, creating a pressure wave that impedes venous filling of the RA, which is in the diastolic phase. In most cases, there is a communication between the left and right atria, resulting from either patency of the foramen ovale or a distinct secundum ASD. The shunt of blood through the septal opening is generally from right to left, but may be bidirectional in some patients. The overall effect of these structural abnormalities on the RA is to produce gross dilation, which may reach enormous proportions, even in infants. This dilation leads to further incompetence of the TV and further widening of the interatrial communication.¹⁴

As a consequence of atrial dilation, atrial tachyarrhythmias are common and become more likely as time goes on. In addition, approximately 15% of patients will have one or more accessory conduction pathways associated with WPW syndrome, and 1% to 2% of patients will have atrioventricular nodal reentrant tachycardia (AVNRT).^{15,16} In end-stage heart failure, ventricular arrhythmias can be present.

CLINICAL PRESENTATIONS

Clinical presentations vary widely, because they depend on the anatomic severity and can range from a severely symptomatic neonate to an asymptomatic octogenarian.¹⁷

The most common presentation varies with age at presentation¹⁸:

- Fetuses: an abnormal routine prenatal scan (86%)
- Neonates: cyanosis (74%)
- Infants: heart failure (43%)
- Children: an incidental murmur (63%)
- Adolescents and adults: arrhythmia (42%), decreased exercise tolerance, fatigue, or right-sided heart failure

Symptoms

Cyanosis and Heart Failure

- Secondary to significant tricuspid regurgitation
- Can appear soon after birth, because of high pulmonary vascular resistance
- Often improves as pulmonary vascular resistance decreases

Exertional Dyspnea, Fatigue, Cyanosis, and Palpitations

- Can occur at a later age
- Can recur and can be insidious in onset

Palpitations

- Secondary to atrial tachyarrhythmia (atrial flutter and fibrillation most common)

- May be present in 20% to 30% of cases
- Some of these arrhythmias are due to WPW syndrome

Paradoxical Embolization

- In the presence of an interatrial communication, patients with Ebstein malformation are at risk for paradoxical embolization, brain abscesses, and sudden death.

Physical Examination

Findings vary with the severity of pathology and the magnitude of right-to-left interatrial shunting.¹⁹

- Murmur and click; commonly mistaken for mitral valve prolapse
- Cyanosis
 - Can be severe in infants
 - Usually milder in older children
 - Digital clubbing will depend on the degree and duration of cyanosis
- Prominent “a” wave in the distended jugular veins
- Hepatomegaly
 - Represents passive hepatic congestion resulting from tricuspid regurgitation and elevated RA pressure
 - Becomes pulsatile because of systolic expansion of the liver
- Palpable, prominent diffuse apical impulse
- Systolic thrill at the left lower sternal border
- Widely split first and second heart sounds, resulting from right bundle branch block
- Prominent S3 or a loud S4 give the impression of multiple heart sounds (triple or quadruple gallop)
- Systolic murmur
 - Secondary to tricuspid regurgitation
 - Increases in intensity with inspiration and may be associated with a mid-diastolic murmur owing to high diastolic flow volume across the tricuspid annulus
 - Can be extremely soft or absent in adults because the low velocity of to-and-fro flow and rapid equalization of pressure across the TV does not result in blood flow turbulence
- Jugular venous pulse rarely showing a large V wave despite severe regurgitation of the TV because the large RA engulfs the increased volume

DIAGNOSTIC WORK-UP

Chest Radiography

The cardiac silhouette varies from almost normal to a markedly enlarged globe-shaped heart with a narrow waist similar to that seen with pericardial effusion (Fig. 130-4). The vascular pedicle is narrow because the pulmonary trunk is not border forming and the ascending aorta, with rare exception, is often small and inconspicuous or absent. Symptomatic neonates can have massive

FIGURE 130-4 ■ **A**, Chest radiograph of a patient with Ebstein malformation with severe tricuspid regurgitation and a small atrial septal defect before tricuspid valve surgery. **B**, Cardiomegaly, a narrow waist, and a cardiothoracic ratio of 0.56 in a neonate with Ebstein malformation showing massive cardiomegaly (“wall-to-wall” heart). (From Said SM, Dearani JA: Ebstein anomaly, congenital tricuspid valve regurgitation and dysplasia. In Allen HD, Driscolle DJ, Shaddy RE, Feltes TF, editors: *Moss and Adams’ heart disease in infants, children, and adolescents*, ed 8, Philadelphia, 2013, Lippincott Williams & Wilkins, Figures 39-11 and 39-12.)

FIGURE 130-5 ■ Electrocardiogram of a patient with severe Ebstein malformation showing the typical changes, with prolongation of the PR interval (226 ms), right bundle-branch block, and somewhat bizarre configuration of the QRS complex. (From Said SM, Dearani JA: Ebstein anomaly, congenital tricuspid valve regurgitation and dysplasia. In Allen HD, Driscolle DJ, Shaddy RE, Feltes TF, editors: *Moss and Adams’ heart disease in infants, children, and adolescents*, ed 8, Philadelphia, 2013, Lippincott Williams & Wilkins, Figure 39-13.)

heart size and outcome is poor if the cardiothoracic ratio is greater than 0.65.

The most consistent and dramatic feature is the enlarged RA silhouette; this is seldom normal, even if the cardiac silhouette is otherwise normal. Lung fields may be normal or decreased because of hypoplasia from severe cardiomegaly (often seen in neonates).

Electrocardiography

Ebstein malformation can be diagnosed using the electrocardiogram, which is rarely normal even with a mild malformation (Fig. 130-5).

The major electrophysiologic changes include the following²⁰:

- Intra-atrial conduction disturbance including PR interval prolongation and tall P waves
- Right bundle branch block
- WPW preexcitation
- Supraventricular tachycardia
- Atrial flutter or fibrillation
- Arrhythmogenic atrialized RV
- Deep Q waves in leads V1–4 and in inferior leads

Complete heart block is rare, but first-degree heart block occurs in 42% of patients because of RA enlargement and the structural abnormalities of the atrioventricular (AV) conduction system.

The AV node may be compressed but is in the normal location. Apical displacement of the septal leaflet is associated with discontinuity of the central fibrous body and the septal AV ring with direct muscular connections,

FIGURE 130-6 ■ Electrocardiogram of a patient with severe Ebstein malformation, showing sinus rhythm with preexcitation (Wolf-Parkinson-White syndrome). A delta wave is noted in the ascending limb of the QRS complex. (From Said SM, Dearani JA: Ebstein anomaly, congenital tricuspid valve regurgitation and dysplasia. In Allen HD, Driscolle DJ, Shaddy RE, Feltes TF, editors: *Moss and Adams’ heart disease in infants, children, and adolescents*, ed 8, Philadelphia, 2013, Lippincott Williams & Wilkins, Figure 39-14.)

creating a substrate for accessory pathways and preexcitation (Fig. 130-6).

More than one accessory pathway is present in 6% to 36% of cases; most of them are located around the orifice of the malformed TV. In addition, wide QRS tachycardia over a septal accessory AV pathway, ventricular tachycardia, as well as ectopic atrial tachycardia, atrial flutter, and atrial fibrillation, can occur.

Echocardiography

Two-dimensional echocardiography is the diagnostic test of choice (Fig. 130-7). More recently, three-dimensional echocardiography is also being used as an adjunct for additional details about TV anatomy. It accurately evaluates the TV and the size and function of different cardiac chambers.

Apical displacement of the septal leaflet by at least 8 mm/m² body surface area is considered a diagnostic feature of Ebstein malformation. The presence of at least three accessory attachments of the leaflet to the ventricular wall confirms leaflet tethering that causes restricted motion of the leaflet.²¹ Marked enlargement of the RA and atrialized RV is present. When the combined area of the RA and atrialized RV is larger than the combined area of the functional RV, left atrium (LA), and LV in the

FIGURE 130-7 ■ Example of an echocardiogram (four-chamber view, apex down) of a patient with severe Ebstein malformation showing a grossly displaced septal leaflet (arrow). The anterior leaflet is severely tethered (“failure of delamination”) and nearly immobile. The atrialized right ventricle (ARV) is large and the functional right ventricle (RV) is small. LA, Left atrium; LV, left ventricle; RA, right atrium. (From Said SM, Dearani JA: Ebstein anomaly, congenital tricuspid valve regurgitation and dysplasia. In Allen HD, Driscoll DJ, Shaddy RE, Feltes TF, editors: *Moss and Adams’ heart disease in infants, children, and adolescents*, ed 8, Philadelphia, 2013, Lippincott Williams & Wilkins, Figure 39-15.)

apical four-chamber view at end diastole, the risk of mortality is increased.

Echocardiography allows assessment of the site and degree of TV regurgitation and the feasibility of valve repair. Ebstein malformation can be diagnosed in utero using fetal echocardiography in as early as the eighteenth week of pregnancy.²² Fetal echocardiography remains a challenge because of the small size of the heart, and it may be difficult to distinguish Ebstein malformation from pulmonary atresia or other causes of TR. Important features that can be determined echocardiographically and that can predict outcome in neonates with Ebstein malformation include the patency of the RV outflow tract and the Great Ormond Street echocardiography (GOSE) score.²³ The GOSE score, as described by Celermajer and colleagues,²³ is calculated in the four-chamber view to create a ratio of the combined areas of the RA and atrialized RV compared with the functional RV, LA, and the LV areas (Fig. 130-8). Patients with the most severe GOSE score (grades 3 and 4) have a poor prognosis (Table 130-2).

Cardiac Catheterization

Cardiac catheterization is rarely necessary, apart from preoperative coronary angiography in older patients. Pulmonary artery pressures are usually normal, although the RV end-diastolic pressure may be elevated. Despite severe TV regurgitation, the RA pressure may be normal, especially with marked RA dilation. Hemodynamic catheterization can also be performed in certain situations when there is LV dysfunction or when there is suspicion of elevated pulmonary artery pressure or elevated LV end-diastolic pressure. This is particularly important if a bidirectional cavopulmonary anastomosis is being considered.

FIGURE 130-8 ■ Great Ormond Street echocardiography (GOSE) score. aRV, Atrialized RV; LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle. (From Knott-Craig CJ, Goldberg SP: Management of neonatal Ebstein’s anomaly. *Semin Thorac Cardiovasc Surg Pediatr Card Surg Annu* 112–116, 2007, Figure 1.)

TABLE 130-2 Mortality Risk by GOSE Score

GOSE score*	Ratio	Mortality
1-2	<1.0	8%
3 (acyanotic)	1.1-1.4	10% early, 45% late
3 (cyanotic)	1.1-1.4	100%
4	>1.5	100%

*GOSE 1, <0.5; GOSE 2, 0.5-1.0; GOSE 3, 1.1-1.4; GOSE 4, >1.5. GOSE, Great Ormond Street echocardiography.

Magnetic Resonance Imaging

Recently, cardiac magnetic resonance imaging has emerged as another tool for evaluation of patients with Ebstein malformation. It provides quantitative measurement of RA and RV size and systolic function, even in the presence of significant distortion of RV anatomy²⁴ (Fig. 130-9). It also provides additional imaging of TV anatomy.

Axial imaging provides a more reliable analysis of disease severity, such as the atrialized RV volume. The ability to create three-dimensional images may provide greater delineation of disease severity. In general, echocardiographic imaging provides detailed valve anatomy and cardiac magnetic resonance imaging provides detailed ventricular anatomy.

NATURAL HISTORY

The prognosis of Ebstein malformation when diagnosed prenatally is poor. In a study of fetuses with Ebstein

FIGURE 130-9 ■ Cardiac magnetic resonance imaging showing systolic and diastolic contours of functional right ventricle and atrialized portion of the right ventricle in (A and B) axial and (C and D) short-axis views. E, Severity index representing the ratio of areas of the right atrium and atrialized right ventricle in numerator and summation of functional right ventricle and left atrium and left ventricular areas in denominator (i.e., Severity index = [Right atrial area + Atrialized right ventricular area] / [Functional right ventricular area + Left atrial area + Left ventricular area]). F, Degree of apical displacement of septal leaflet of tricuspid valve (in millimeters) measured in ventricular diastole. aRV, Atrialized right ventricle; fRV, functional right ventricle; LA, left atrium; LV, left ventricle; RA, right atrium. (A-D from Yalonetsky S, Tobler D, Greutmann M, et al: Cardiac magnetic resonance imaging and the assessment of Ebstein anomaly in adults. *Am J Cardiol* 107:767-773, 2011, Figure 2.)

malformation or TV dysplasia from Children's Hospital Boston, eight (24% of 33) pregnancies were terminated, nine (27%) fetuses died in utero, and 16 (49%) fetuses survived to birth. Only seven (21% of 33) prenatally diagnosed patients survived beyond the neonatal period.²⁵ Survival was related to the severity of Ebstein malformation and the presence of RV or LV dysfunction. Elective early delivery may be needed in fetuses that exhibit signs of distress.

It is not uncommon for Ebstein malformation to be undiagnosed until adulthood. The oldest patient in the Mayo surgical series was 79 years old at time of diagnosis and subsequent surgery. However, late diagnosis is also associated with reduced survival. The mean age of diagnosis in a study of the natural history of 72 unoperated patients was 23.9 ± 10.4 years. In this group of patients,

arrhythmias were the most common clinical presentation (51%).²⁶ The estimated cumulative overall survival rates were 89%, 76%, 53%, and 41% at 1, 10, 15, and 20 years of follow-up, respectively. Predictors of cardiac-related death on univariate analysis included (1) cardiothoracic ratio of 0.65 or greater, (2) increasing severity of TV displacement on echocardiography, (3) New York Heart Association (NYHA) class III or IV, (4) cyanosis, (5) severe TR, and (6) younger age at diagnosis. However, in a multivariate model, younger age at diagnosis, male sex, cardiothoracic ratio of 0.65 or greater, and the severity of TV leaflet displacement on echocardiography were predictors of late cardiac mortality.

MANAGEMENT

Neonates and Infants

Indications for Operation

In neonates or infants who remain in congestive heart failure or are profoundly cyanotic, operative therapy is required. In the newborn period, three pathways can be considered: the biventricular repair (Knott-Craig approach),²⁷ single-ventricle repair (i.e., RV exclusion technique, or Starnes approach), and cardiac transplantation.

Biventricular Repair (Knott-Craig Approach). In this approach, the TV is repaired and the ASD is partially closed. This is a monocusp type of valve repair based on a satisfactory anterior leaflet.²⁸ The subtotal closure of the ASD allows right-to-left shunting, which may be necessary in the early postoperative period when there is a high risk of RV dysfunction or elevated pulmonary vascular resistance. RA reduction is performed routinely and is important to reduce the size of the markedly enlarged heart to allow room for the lungs (Fig. 130-10).

The postoperative care of a newborn after a biventricular repair can be challenging. Delayed sternal closure is used liberally. Tolerance of early low peripheral oxygenation is common, and inhaled nitric oxide may be necessary to decrease pulmonary vascular resistance. Prophylactic use of a peritoneal dialysis catheter can also be used to ensure complete decompression of the abdomen.

Although early mortality for this operation is high (25%-30%), the intermediate outcome with the biventricular approach appears to be promising. In 2007, Knott-Craig and colleagues²⁹ published their experience with 27 neonates and young infants. These patients had concomitant anatomic or functional pulmonary atresia ($n = 18$), ventricular septal defect ($n = 3$), small LV ($n = 3$), and hypoplastic branch pulmonary arteries ($n = 3$). Twenty-five patients received a biventricular repair, with TV repair in twenty-three and valve replacement in two. Survival to hospital dismissal was 74%; risk was greater when there was anatomic pulmonary atresia. There were no late deaths (median follow-up, 5.4 years; maximum, 12 years). All patients were in functional NYHA class I. Although these early results for repair of Ebstein malformation during the neonatal period are poor compared with many other neonatal anomalies corrected in the first

FIGURE 130-10 ■ Biventricular repair of neonatal Ebstein (Knott-Craig). **A**, Partition of the tricuspid valve orifice into two openings by approximation of the annuloplasty stitch. **B**, Once the valve is judged to be competent, the “caudal” orifice is closed, thereby plicating the atrialized portion of the right ventricle. **C**, Creation of a competent monocuspid valve by taking down the anterior leaflet from the annulus, fenestrating it, and augmenting it with a pericardial patch. **D**, The atrial septal defect (ASD) is closed with a fenestrated patch, and an annuloplasty stitch is placed with one pledgeted end in the coronary sinus and the other pledgeted end at the location of the commissure between anterior and posterior leaflets. (From Knott-Craig CJ, Goldberg SP: Management of neonatal Ebstein’s anomaly. *Semin Thorac Cardiovasc Surg Pediatr Card Surg Annu* 112–116, 2007, Figures 4, 5, and 6.)

FIGURE 130-11 ■ Starnes repair of neonatal Ebstein malformation. ASD, Atrial septal defect. (From Knott-Craig CJ, Goldberg SP: Management of neonatal Ebstein’s anomaly. *Semin Thorac Cardiovasc Surg Pediatr Card Surg Annu* 112–116, 2007, Figure 2.)

month of life (e.g., arterial switch procedure, Norwood stage I), they have become a benchmark for this difficult patient population.

Right Ventricular Exclusion (Starnes Approach).

Alternatively, the RV exclusion approach, pioneered by Starnes and colleagues,³⁰ involves fenestrated patch closure of the TV orifice, enlarging the interatrial connection, and placing a systemic-to-pulmonary artery shunt (Fig. 130-11). This approach is particularly appealing in patients who also have anatomic pulmonary atresia or other important RV outflow tract obstruction. A small fenestration (using a 4- to 5-mm punch) is placed in the TV patch to allow RV decompression as it passively fills with blood from the thebesian veins.³¹ This also allows progressive involution of the enlarged dysfunctional RV, which is helpful in the long term when preparing for the

eventual Fontan procedure.³² In patients who have a patent RV outflow tract, a competent pulmonary valve is required to prevent blood from entering the RV, resulting in RV distention. If patients have an incompetent pulmonary valve, the main pulmonary artery should be ligated or the incompetent pulmonary valve should be closed. These issues must be considered because significant dilation of a poorly functioning RV eventually results in compression and impairment of LV function. Similar to the biventricular approach, RA reduction is routinely performed to allow space for the lungs.

Modified Starnes Approach (Total Ventricular Exclusion). A modification to the Starnes single-ventricle approach, total RV exclusion, has been advocated by Sano and associates,³³ in which the free wall of the RV is resected and closed primarily or with a polytetrafluoroethylene patch. This procedure acts like a large RV plication and RV volume reduction procedure (Fig. 130-12). This adaptation of the Starnes method may improve LV filling and provide additional space for the lungs and decompression of the LV.

Postoperative care is similar to that of any shunt-palliated patient with a univentricular heart. Optimizing systemic perfusion and obtaining adequate oxygenation is the primary goal. Delayed sternal closure and peritoneal drainage are also beneficial. As with other patients with a shunt-dependent pulmonary circulation, careful surveillance is required between the first operation and the second-stage procedure (bidirectional cavopulmonary shunt), which is usually performed at 3 to 6 months of age.

Results of the single-ventricle pathway have been reported by Reemtsen and colleagues.³⁴ Of 16 neonates, two patients had TV repair, one patient had heart transplant, 10 patients had a RV exclusion procedure with a fenestrated TV patch, and three patients had a RV exclusion procedure with a nonfenestrated TV patch. The

FIGURE 130-12 ■ Sano "RV exclusion" procedure. ASD, Atrial septal defect; RV, right ventricle; TV, tricuspid valve. (From Knott-Craig CJ, Goldberg SP: Management of neonatal Ebstein's anomaly. *Semin Thorac Cardiovasc Surg Pediatr Card Surg Annu* 112–116, 2007, Figure 3.)

operative survival was 80% (8 of 10) in patients with a fenestration, and 33% in patients with no fenestration, leading the authors to recommend fenestration of the TV patch. Among the nine hospital survivors of RV exclusion, three underwent completion of the Fontan, and all nine have had a successful bidirectional cavopulmonary shunt (second stage).

Heart Transplantation. Heart transplantation remains an option in the most severe cases of Ebstein malformation, but it is rarely necessary in the current era because of the improved results with the Knott-Craig and Starnes approaches. Limitations of heart transplantation include the scarcity of donor organs in the neonatal age group and the side effects of long-term immunosuppression and its associated complications in the transplant recipient. Finally, the development of smaller ventricular assist devices and advances in extracorporeal membrane oxygenation has provided mechanical support options in the perioperative period for these infants.

Children and Adults

Indications for Operation

Although medical management, including diuretics and antiarrhythmic drugs, can be used to manage some of the symptoms of heart failure and arrhythmias, eventually most patients require operation. Observation alone is usually advised for asymptomatic patients with no right-to-left shunting, mild cardiomegaly, and normal exercise tolerance. Most patients in NYHA class I or II can be managed medically. Operation is offered when symptoms are present (fatigue most common), increasing cyanosis becomes evident, or if paradoxical embolism occurs. Operation is also advised if there is objective evidence of deterioration, such as decreasing exercise performance by exercise testing, progressive increase in heart size on chest radiography, progressive RV dilation or reduction of systolic RV function by echocardiography, or appearance of atrial or ventricular arrhythmias. In borderline situations, the echocardiographic determination of high

probability of TV repair makes the decision to proceed with operation easier. In our practice, we advise operation between 2 and 5 years of age because of our ability to successfully perform an anatomic (cone-type) repair in 95% to 98% of children. Once symptoms develop and patients progress to NYHA class III or IV, medical management has little to offer; operation then becomes the only chance for improvement.

A biventricular repair is possible for the vast majority of patients. In some circumstances, a 1.5-ventricle repair (adding a bidirectional cavopulmonary shunt) is advantageous when there is significant RV dilation or dysfunction, or if the resultant TV repair has a small effective orifice (uncommon). The bidirectional cavopulmonary shunt can also reduce hemodynamic stress on a more complex TV repair, because the volume of the RV is decreased by 35% to 45%, depending on the patient's age. Cardiac transplantation is rarely indicated and is reserved for patients with severe biventricular dysfunction.

Operative Management

Our operative management of patients with Ebstein malformation consists of (1) closure of any atrial septal communications (except during infancy); (2) correction of associated anomalies (e.g., closure of ventricular septal defect); (3) performance of any indicated antiarrhythmia procedures, such as the maze procedure (cryoablation or radiofrequency ablation), surgical division of accessory conduction pathways, or cryoablation of AVNRT; (4) internal plication (apex to base) of the atrialized portion of the RV; (5) repair of the TV; and (6) right reduction atrioplasty. In the current era, intraoperative electrophysiologic mapping for localization of accessory conduction pathways in patients with ventricular preexcitation is rarely required. When preexcitation is present, preoperative mapping and ablation is performed in the catheterization laboratory. Intraoperative transesophageal echocardiography is used routinely.

Anatomic Cone Repair. Anatomic variability of EM continues to be a challenge for the surgeon since the earliest repair techniques in 1958.^{35,36} Most repair techniques address the abnormal TV in a manner that focuses on the concept of monocusp repair.³⁷ Monocusp repair depends on an adequate anterior leaflet with a freely mobile leading edge that allows coaptation with the ventricular septum. Significant degrees of RV or annular dilation or significant tethering of the anterior leaflet can preclude a successful monocusp repair.

The early Mayo Clinic experience focused on the Danielson monocusp repair, and the use of the Sebens stitch (suture attachment of the anterior papillary muscle to the ventricular septum) was common. The French experience (Carpentier)³⁸ focused on mobilization (surgical delamination) of the anterior leaflet with annular reattachment, resulting in an anterior leaflet monocusp repair. The Brazilian experience (da Silva) was an extension of the French technique. The difference was surgical delamination of all available leaflet tissue, with approximated circumferential leaflets anchored at the true annulus resulting in a "cone" of leaflet tissue. The

Brazilian experience with cone repair in 52 patients has been reported.^{39,40} Mean age was 18.5 ± 13.8 years, and mean follow-up was 57 ± 45 months. There were two early deaths (3.8%) and two late deaths. The Brazilian group also reported an increase in the indexed RV functional area in the early preoperative period; however, that remained unchanged at intermediate follow-up. The reduction of TR was maintained at intermediate follow-up.

Operation for EM is performed through sternotomy using cardiopulmonary bypass, aortic and bicaval cannulation with cross-clamping, and cold blood

cardioplegia. The principle of cone repair (CR) is complete surgical delamination and recruitment of all undelaminated leaflet tissue, which is reanchored at the true right AV junction, creating a 360-degree "leaflet cone." Leaflet-to-leaflet approximation is generally done with interrupted monofilament sutures to avoid a pursestring effect that can decrease the height of the reconstructed leaflet (Fig. 130-13). The atrialized, inferior RV (i.e., smooth and not trabeculated) is plicated internally from "apex to annulus." The plication typically crosses the true annulus to partially reduce the size of the dilated annulus (Fig. 130-14). Care is taken to avoid distortion or

FIGURE 130-13 ■ Operative steps for the da Silva technique for Ebstein anomaly repair. **A**, The first incision is made with a no. 15 blade in the anterior leaflet at the twelve-o'clock position; the incision is a few millimeters away from the true annulus. The incision is then extended rightward in a clockwise fashion using a scissors. It is common for there to be a true space between the anterior leaflet and the right ventricle in this region (i.e., normally delaminated leaflet). However, when the transition is met between the anterior and inferior (posterior) leaflets, it is common for there to be failure of delamination (*inset*) resulting in fibrous and muscular attachments between the leaflet and myocardium. The diagram demonstrates the scissors approaching the area where there is some adherence of leaflet tissue to the underlying myocardium. Dissection continues such that a portion of distal anterior leaflet and some inferior leaflet tissue is surgically delaminated. The most important aspect of this surgical delamination is to incise all fibrous and muscular attachments between the body of the leaflet and the right ventricular myocardium, but to maintain intact all fibrous (and occasionally muscular) attachments of the leading edge of the leaflet to the underlying myocardium. Importantly, do not disrupt chordal attachments to the leading edge of any leaflet. **B**, As the anterior and surgically delaminated inferior leaflet is reflected away from the right ventricular myocardium, all fibrous and muscular attachments into the body of the underside of the leaflet are incised as shown with the scissors. It is important to keep all attachments of the leading edge of the leaflet intact. If the edge is linearly attached, then surgical fenestrations are created as depicted earlier. The *dotted triangle* represents the atrialized right ventricle. **C**, Dissection is continued with a scissors, with the goal of taking down all attachments between the septal leaflet and myocardium but preserving all attachments of the leading edge to the endocardium as described above. The dissection should proceed medially to the antero-septal commissure. The leaflet tissue is typically fragile and thin in this area. There can be marked variability in the status of the leading edge of the septal leaflet, as was described for the anterior and inferior leaflets. If there is a linear attachment, then surgically created fenestrations are also made in this leaflet (not shown). **D**, The mobilized anterior and inferior (posterior) leaflets. Natural fenestrations are shown at the junction of the anterior and inferior leaflets (*arrows*). LV, Left ventricle; RA, right atrium; RV, right ventricle. (From Said SM, Dearani JA: Ebstein anomaly, congenital tricuspid valve regurgitation and dysplasia. In Allen HD, Driscoll DJ, Shaddy RE, Feltes TF, editors: *Moss and Adams' heart disease in infants, children, and adolescents*, ed 8, Philadelphia, 2013, Lippincott Williams & Wilkins, Figure 39-22AD.)

FIGURE 130-14 ■ **A**, After the anterior, inferior, and septal leaflets are completely mobilized, the cut edge of the inferior leaflet is rotated clockwise to meet the proximal edge that has been prepared on the mobilized septal leaflet. The two leaflets are approximated with interrupted fine monofilament sutures completing the cone reconstruction. This results in 360 degrees of leaflet tissue that will compose the new tricuspid valve orifice. **B**, After the cone reconstruction is completed, the atrialized right ventricle (RV) is examined to determine whether plication is necessary. Note the position of the right coronary artery (RCA) in the true tricuspid valve annulus and that the main RCA or the posterior descending coronary artery can be compromised. This figure demonstrates the technique for internal plication of the atrialized right ventricle from apex to base. Monofilament suture is used; the suture is begun distally toward the apex of the right ventricle. It is important to conduct frequent examinations of the outside of the inferior wall of the right ventricle to ensure that inadvertent compromise of the right coronary artery is avoided. **C**, The suture line is advanced toward the base of the heart (i.e., toward the atrioventricular groove). As the dotted lines of the triangle are effectively approximated, the atrialized RV is excluded. The suture line sometimes crosses the atrioventricular groove to reduce the size of the dilated annulus. After the sides of the triangle are approximated, the entrance into the excluded atrialized segment of the right ventricle is then closed to eliminate the “blind pouch.” **D**, After the plication is completed, the newly constructed tricuspid valve is then reattached at the level of the true tricuspid annulus. Because the neotricuspid valve will have an orifice that is smaller than the original dilated atrioventricular junction, a plication of the inferior annulus is usually necessary to meet the size of the smaller neotricuspid valve. Reattachment of the septal leaflet should be done to the ventricular septum and to the ventricular side of the conduction tissue, which is usually marked by a small vein (Vein of D). AL, Anterior leaflet; SL, septal leaflet. (**A**, **C**, and **D** from Said SM, Dearani JA: Ebstein anomaly, congenital tricuspid valve regurgitation and dysplasia. In Allen HD, Driscolle DJ, Shaddy RE, Feltes TF, editors: *Moss and Adams’ heart disease in infants, children, and adolescents*, ed 8, Philadelphia, 2013, Lippincott Williams & Wilkins, Figure 39-22. **B** from Dearani JA, Said SM, O’Leary PW, et al: Anatomic repair of Ebstein’s malformation: lessons learned with cone reconstruction. *Ann Thorac Surg* 95:220–226, discussion 226–228, 2013, Figure 3A.)

compromise of the right coronary artery that is located in the AV groove. Additional inferior annular plication is done as needed to reduce annular size to match the size of the neo-tricuspid valve (neoTV; Fig. 130-15A); this area also requires reinforcement with pledgeted mattress sutures. When there is a marked size discrepancy between the neoTV and true annulus, annular plication is performed at multiple sites around the anterior and inferior annuli to avoid an exaggerated plication in one location that could compromise the right coronary artery (see Fig. 130-15B). Reattachment of the neoTV to the true annulus

is done with interrupted or continuous suture; continuous suture does pursestring the annulus, causing further reduction in annular size, which may be desired when significant annular reduction is needed.

A flexible annuloplasty band—anteroseptal commissure clockwise to inferoseptal commissure with anchoring in the coronary sinus—is used to stabilize the repair as the tricuspid annulus is usually dilated (Fig. 130-16A). The normal adult TV annular size is 20 to 24 mm; the adult ring size is most often a 26- or 28-mm ring. The use of a 26- or 28-mm ring is usually possible in many

FIGURE 130-15 ■ Technique of tricuspid annular plication. This can be performed in a single inferior (**A**) or multiple (**B**) anterior and inferior sites of the annulus. Multiple plication sites help to avoid an exaggerated plication in one location that could compromise the right coronary artery (RCA). (From Dearani JA, Said SM, O'Leary PW, et al: Anatomic repair of Ebstein's malformation: lessons learned with cone reconstruction. *Ann Thorac Surg* 95:220–226, discussion 226–228, 2013, Figure 1AB.)

FIGURE 130-16 ■ **A**, The tricuspid annulus is usually dilated, and a flexible annuloplasty ring is typically used when somatic growth is complete. **B**, In younger patients when somatic growth is not complete, an eccentric ring confined to the inferior annulus (anteroinferior to inferoseptal commissures) can be used. RCA, Right coronary artery. (From Dearani JA, Said SM, O'Leary PW, et al: Anatomic repair of Ebstein's malformation: lessons learned with cone reconstruction. *Ann Thorac Surg* 95:220–226, discussion 226–228, 2013, Figure 2AB.)

FIGURE 130-17 ■ **A**, Reattachment of the septal leaflet (SL) should be done to the ventricular side of the conduction tissue (dotted line arrow), which is usually marked by a small vein (Vein of D). **B**, Intraoperative photograph showing the reattachment of the completely mobilized tricuspid valve leaflets. AL, Anterior leaflet. (From Dearani JA, Said SM, O'Leary PW, et al: Anatomic repair of Ebstein's malformation: lessons learned with cone reconstruction. *Ann Thorac Surg* 95:220–226, discussion 226–228, 2013, Figure 3AB.)

younger patients (≈ 6 years old) because the starting size of the annulus is often much larger. When somatic growth is a concern, eccentric partial ring support from anteroinferior to inferoseptal commissure (down to coronary sinus) is used, because this is the area most vulnerable to annular dilation (see Fig. 130-16B). The septal leaflet reattachment is performed to the ventricular side of the conduction tissue. All suture lines are done twice for reinforcement. The reanchoring of the neoTV of circumferential leaflet tissue surrounding the tricuspid orifice with its hinge point at the AV groove mimics normal TV anatomy—namely, an anatomic repair (Fig. 130-17).

Adjuncts to Cone Repair. In addition to ring placement, other modifications that we applied selectively to CR to optimize a successful repair include:

1. Leaflet augmentation with Cor Matrix membrane (Cor Matrix Cardiovascular, Santa Cruz, CA) or autologous pericardium to increase leaflet height (Fig. 130-18)
2. Cone augmentation with a small triangular patch to avoid tricuspid stenosis (Fig. 130-19)
3. Leaflet plication to increase leaflet height
4. Surgical fenestrations to create autologous neo-chordae when a linear attachment is present (Fig. 130-20)

FIGURE 130-18 ■ Tricuspid valve anterior leaflet augmentation can be performed using Cor Matrix membrane or autologous pericardium to increase the leaflet height and to improve surface area coaptation. Several small plications along the annular free edge of the leaflet can also be performed to increase the leaflet height. (From Dearani JA, Said SM, O’Leary PW, et al: Anatomic repair of Ebstein’s malformation: lessons learned with cone reconstruction. *Ann Thorac Surg* 95:220–226, discussion 226–228, 2013, Figure 4.)

FIGURE 130-19 ■ A triangular patch is used to augment the reconstructed cone to avoid tricuspid valve stenosis when there is a paucity of septal leaflet tissue and absent inferior leaflet. (From Dearani JA, Said SM, O’Leary PW, et al: Anatomic repair of Ebstein’s malformation: lessons learned with cone reconstruction. *Ann Thorac Surg* 95:220–226, discussion 226–228, 2013, Figure 5.)

5. The Sebening stitch, which involves approximation of the mobilized “base-intact” anterior papillary muscle to the ventricular septum (Fig. 130-21B)
6. Modified Sebening stitch that involves approximation of the head of the mobilized “base-intact” RV free wall papillary muscle to a corresponding head of a papillary muscle arising from the ventricular septum supporting the septal leaflet (as opposed to anterior papillary muscle approximation to the ventricular septum; see Fig. 130-21A)
7. Artificial Gore-Tex (WL Gore, Flagstaff, AZ) chordae

FIGURE 130-20 ■ A and B, In the presence of a linear attachment where the leading edge is completely adherent, surgical neo-chordae are created by making several fenestrations apically in the distal portion of the leaflet to allow unrestricted forward blood flow into the ventricle. (From Dearani JA, Said SM, O’Leary PW, et al: Anatomic repair of Ebstein’s malformation: lessons learned with cone reconstruction. *Ann Thorac Surg* 95:220–226, discussion 226–228, 2013, Figure 6AB.)

Leaflet augmentation is applied when the height of the anterior leaflet is shallow or when the rotated cone will result in a smaller than normal orifice. Importantly, when leaflet augmentation is used, the patch is placed between the mid leaflet and annulus and should never involve the leading edge. Importantly, the patch is kept as small as possible.

Relative contraindications to the cone reconstruction include older age (>60 years), moderate pulmonary hypertension, significant LV dysfunction (ejection fraction < 30%), absent septal leaflet, poor delamination or poor quality of the anterior leaflet (i.e., <50% delamination of the anterior leaflet), and severe muscularization of the anterior leaflet not amenable to sufficient debulking to obtain a pliable leaflet. Severe RV enlargement and severe dilation of the right AV junction (true tricuspid annulus) can also make successful CR challenging because there is significant stress on the many suture lines necessary to perform the CR.

In 2007, Dr. da Silva published his series of 40 patients who underwent the cone reconstruction.³⁹ In this series, the operative mortality was one patient (2.5%). After a mean follow-up of 4 years (range, 3 months to 12 years), only one patient died and two patients required late TV re-repair. The cone technique has the potential to cause TV stenosis, particularly when there is a paucity of leaflet tissue, although no patients in this initial cohort experienced this complication. Additional follow-up is required to determine whether this method of repair has long-term durability.

Tricuspid Valve Re-Repair. Although challenging, TV re-repair is still possible in Ebstein malformation. We have reported our experience with TV re-repair for Ebstein malformation previously.⁴¹ This has been

FIGURE 130-21 ■ **A**, The modified Sebening stitch in which the head of the mobilized right ventricular free wall papillary muscle is approximated to the corresponding smaller head of a septal papillary muscle (as opposed to approximation to the ventricular septum in the original Sebening stitch). **B**, It is important to avoid dimpling of the right ventricular free wall, as this indicates excessive tension. LA, Left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle. (From Dearani JA, Said SM, Burkhart HM, et al: Strategies for tricuspid re-repair in Ebstein malformation using the cone technique. *Ann Thorac Surg* 96:202–208, discussion 208–210, 2013, Figure 5AB.)

FIGURE 130-22 ■ A surgeon's view into the right atrium; the patient's head is to the left. **A**, The anterior leaflet has been detached from the annulus. There is a linear attachment of the leading edge of the anterior leaflet with a direct papillary muscle insertion (black arrow). **B**, The anterior leaflet was mobilized and is being prepared to be reattached to the anterior annulus. The dotted line arrow identifies the previous ring, which was the only repair maneuver at the initial operation. (From Dearani JA, Said SM, Burkhart HM, et al: Strategies for tricuspid re-repair in Ebstein malformation using the cone technique. *Ann Thorac Surg* 96:202–208, discussion 208–210, 2013, Figure 1AB.)

performed in 32 patients to date; our previous report of 20 patients demonstrated a median age of 15 years (range, 4 to 68 years). Four patients (20%) had prior bidirectional cavopulmonary anastomosis. Preoperative heart failure was present in eight patients (40%). Recurrent tricuspid regurgitation was due to incomplete leaflet coaptation with tethered anterior leaflet in all patients; and 10 patients (50%) had diminutive septal leaflet. This was possible because prior repair techniques focused on annuloplasty maneuvers in all patients with no or incomplete surgical delamination of leaflet tissue (Fig. 130-22). Re-repair strategies followed the previously mentioned cone reconstruction principles with complete 360 degree mobilization and recruitment of all available leaflet tissues.

There have been no early or late deaths in this group. Mean follow-up was 7.7 ± 10.7 months; during follow-up, 18 patients had no or mild TR and 2 patients had moderate TR.

Tricuspid Valve Replacement. Tricuspid valve replacement remains a reasonable option in those patients who cannot undergo valve repair. In our experience, the most common reason for the inability to obtain a satisfactory CR is significant muscularization of the anterior leaflet not amenable to debulking or resection, or absent septal leaflet; this is determined intraoperatively. Other indications to consider valve replacement include relative older age (>60 years) or massive RV or annular dilation; this is also ultimately determined intraoperatively. We have previously reported good durability with porcine bioprostheses in patients with EM. However, our preference is always to repair the TV whenever possible, and with our

larger experience we have learned that it is feasible for almost all patients.

Bioprosthetic (porcine) valve replacement, as opposed to mechanical valve replacement, is generally preferred because of relative good durability of the porcine bioprosthesis in the tricuspid position and the lack of need for warfarin anticoagulation.⁴² Bioprosthetic valves do not have the thromboembolic complications of mechanical valves, but they require warfarin anticoagulation for the first 3 to 6 months postoperatively. Mechanical valves in the tricuspid position are sometimes associated with a higher frequency of valve malfunction and thrombotic complications compared with mechanical valves in other cardiac positions, particularly when RV function is poor⁴³ and discs do not open and close properly.

When the TV cannot be reconstructed and replacement is necessary, the suture line is deviated to the atrial side of the AV node and membranous septum to avoid injury to the conduction mechanism. A small vein crossing the tricuspid annulus adjacent to the membranous septum typically marks the AV node. To avoid injury to the right coronary artery, the anterior suture line is deviated toward the atrial side of the TV annulus anteriorly (where the smooth and trabeculated portions of the RA meet each other) and posterolaterally where the tissues are frequently thin. The coronary sinus can be left to drain into the RA if there is sufficient room between it and the AV node; if the distance is short, the coronary sinus can be left to drain into the RV so that heart block can be avoided. The struts of the porcine bioprosthesis are oriented so that they straddle the area of the membranous septum and conduction tissue. The valve sutures are tied with the heart beating (after intracardiac

communications are closed) to detect any disturbances in AV conduction. Tricuspid replacement also has the advantage of a short cross-clamp time (after ASD closure), which may be preferred when mild or moderate LV dysfunction is present or when there is surgeon inexperience or low confidence with a difficult tricuspid repair that might result in a prolonged cardiac ischemic time.

The 1.5-Ventricle Repair. We use the bidirectional cavopulmonary shunt selectively; it is applied in approximately 20% of patients undergoing operation. The bidirectional cavopulmonary shunt is helpful when the RV is severely dilated and functioning poorly. Although uncommon, it can also be applied when a successful TV repair has resulted in an effective valve orifice that has mild to moderate stenosis (mean gradient > 6 mm Hg). Because concomitant LV dysfunction may be present in advanced stages, it is important to document by direct pressure measurements that the pulmonary arterial and LA pressures are low; otherwise, the bidirectional cavopulmonary shunt will not be feasible. If the LV end-diastolic pressure is less than 12 mm Hg, the transpulmonary gradient is less than 10 mm Hg, and the mean pulmonary arterial pressures are less than 18 mm Hg, a bidirectional cavopulmonary shunt is permissible. Even in the presence of moderate LV dysfunction (an ejection fraction of 35% to 40%), it is usually feasible to perform a bidirectional cavopulmonary shunt in the setting of Ebstein malformation.

Others have suggested that the construction of a bidirectional cavopulmonary shunt may allow for less than perfect TV repairs, because LV filling is not completely dependent on forward flow through the RV.⁴⁴ In addition, the shunt may allow patients to tolerate longer intervals between repeated TV operations for progressive tricuspid regurgitation or failing TV prostheses. This may be due to the smaller regurgitant volume and therefore a decreased volume load to the RV.

Chavaud and colleagues⁴⁵ and Quiñonez and coworkers⁴⁶ have proposed that the use of a bidirectional cavopulmonary shunt can decrease operative mortality and facilitate the postoperative management when there is severe RV dysfunction. The literature suggests that the frequency of bidirectional cavopulmonary shunt application in patients with Ebstein malformation is increasing: in a series of 150 patients in a European registry, almost 26% underwent a 1.5-ventricle repair. Although the early results appear to be improved, late results of a bidirectional cavopulmonary shunt in patients with Ebstein malformation are unknown.

Disadvantages of the bidirectional cavopulmonary shunt include pulsations of the head and neck veins, facial swelling, and the development of arteriovenous fistulae in the pulmonary vasculature. In addition, the placement of this shunt compromises access to the heart from the internal jugular approach for electrophysiologic studies and for pacemaker lead placement. The bidirectional cavopulmonary shunt has promising applications in the management of patients with Ebstein malformation, particularly those with RV failure, but it is our belief that it should be reserved for these selected patients until the late outcomes are well described.

Surgical Treatment of Arrhythmias. The most common atrial tachyarrhythmias in Ebstein malformation are atrial fibrillation and flutter. We have successfully used the right-sided cut-and-sew lesions of Cox-Maze III procedure in the early era of maze surgery and now use the modified RA maze lesions when arrhythmia surgery is applied. With the availability of newer devices, such as radiofrequency or cryoablation, the procedure time for maze procedure is shortened significantly. Consequently, our current preference is to perform a biatrial maze procedure when there is chronic atrial fibrillation, LA dilation, or concomitant mitral regurgitation. We follow the lesions in both atria that have been described previously.^{47,48} In the presence of atrial flutter, we prefer to add a "cavotricuspid isthmus" lesion, which is the posterolateral TV annulus to the coronary sinus to the inferior vena cava. We also make an effort to close the LA appendage.

In patients with AV nodal reentrant tachycardia who underwent unsuccessful ablation in the electrophysiologic laboratory preoperatively, we perform perinodal cryoablation on cardiopulmonary bypass after opening the RA and closure of the intracardiac shunt. This involves multiple applications of the cryoprobe around and in the os of the coronary sinus, which is then carried anteriorly toward the proximal AV node until temporary complete heart block is noted, at which time the rewarming is begun; normal AV conduction returns shortly thereafter. In case of accessory conduction pathway as in WPW syndrome, mapping and ablation is performed preoperatively. Intraoperative mapping and ablation is rarely performed in the current era.

Heart Transplantation. Transplantation is an option in patients with Ebstein malformation with severe biventricular dysfunction (i.e., LV ejection fraction < 25%). In our experience, patients with severe RV dysfunction and normal or mild to moderately depressed LV function can be managed with a conventional operation, which can include placement of a bidirectional cavopulmonary shunt at the time of tricuspid repair or replacement. Other patients with Ebstein malformation who should be considered for transplantation are those with significant LV dilation and dysfunction or those with severe nonstructural mitral regurgitation with significant LV dysfunction. Hemodynamic cardiac catheterization to ascertain left-sided filling pressures and pulmonary artery pressures is also helpful in this group of patients when trying to determine feasibility of conventional operation versus transplantation.

POSTOPERATIVE CARE

Early postoperative management begins in the operating room. Discontinuation of bypass is accomplished with epinephrine and milrinone. To minimize RV dilation, higher heart rates (100 to 120 beats/min) are preferred and are obtained with temporary atrial pacing if needed. Low-dose vasopressin can be helpful with right-sided heart failure because systemic vasoplegia is not uncommon in this group of patients. This may be due to the use

preoperative afterload reducing agents, liver congestion, or humoral factors from atrial natriuretic peptide secondary to atrial dilation.

Volume administration should be done cautiously to avoid RV distention; RA pressures less than 10 to 12 mm Hg are preferred. This strategy can result in mild metabolic acidosis in the early postoperative period but is tolerated as long as urine output is satisfactory and peripheral perfusion is normal. Extubation is performed after metabolic parameters have normalized (≈ 12 hours). Nitric oxide can be helpful to offset the pulmonary vasoconstrictive effects of inotropic support, thereby reducing afterload to the dysfunctional RV.

Medical therapy at hospital discharge includes beta blocker or angiotensin-converting enzyme inhibitor, or both, and selective use of sildenafil for 6 to 8 weeks for patients who have mildly elevated pulmonary artery pressures or for patients who live at high altitude. Importantly, amiodarone therapy is used for 2 to 3 months when there are documented arrhythmias and frequently when RV plication has been performed. Long-term arrhythmia surveillance with appropriate exercise testing is essential with this diagnosis.

OUTCOMES

Our experience with surgery for Ebstein malformation now approaches 1000 patients. Analysis of various groups of patients within this large cohort has been published previously.⁴⁹ We have performed 170 cone repairs to date; our initial experience was published recently.⁵⁰ Between June 2007 and December 2011, 89 patients (47 female; 53%) underwent cone reconstruction (median age, 19 years; range, 19 days to 68 years). The indications for operation were progressive cardiomegaly in 43 (48%), cyanosis in 29 (33%), and heart failure in 13 (15%). Prior TV repair was performed in 12 patients (13%). Severe tricuspid regurgitation (TR) was present in 75 patients (84%). All patients underwent cone reconstruction. Modifications included ringed annuloplasty in 57 patients (64%), leaflet augmentation in 28 patients (31%), and autologous chordae in 17 patients (19%). Bidirectional cavopulmonary anastomosis was performed in 21 patients (24%). Early mortality occurred in 1 patient (1%). Early reoperation for recurrent TR occurred in 12 patients (13%); re-repair was performed in 6 patients (50%), and 6 (50%) required replacement. Mean follow-up was 19.7 ± 24.7 months. There was no late mortality or reoperation. At follow-up, 72 patients (87%) had no or mild TR, 9 patients (11%) had moderate TR, and 2 patients (2%) had severe TR. Ringed annuloplasty was associated with less than moderate TR at dismissal ($P = 0.01$).

Most of the literature focuses on survival and reoperation, with little discussion about the functional outcome for patients with Ebstein malformation after surgery. We reported our experience of 539 patients with Ebstein malformation (pre-cone era) who underwent 604 cardiac operations.⁵¹ The mean age at the initial operation was 24 years (range, 8 days to 79 years) and 53% were female. Survival at 5, 10, 15, and 20 years was 94%, 90%, 86%, and 76%, respectively. Survival free of late reoperation

was 86%, 74%, 62%, and 46% at 5, 10, 15, and 20 years, respectively. Two hundred and thirty-seven (83%) patients were in NYHA functional class I or II, and 34% were taking no cardiac medication. The reported exercise tolerance was comparable to that of the patients' peers. In a small subset of these patients, formal exercise testing was conducted. There was improvement in exercise tolerance after operation, but this improvement was believed to be a result of the elimination of the right-to-left shunt at the atrial level rather than improvement in ventricular function. Late reoperation, rehospitalization, and atrial tachyarrhythmias continue to be a problem, with a rate of freedom from rehospitalization (for cardiac causes including reoperation) of 91%, 79%, 68%, 53%, and 35% at 1, 5, 10, 15, and 20 years, respectively. Thus, further improvement in the durability of TV repair and replacement, as well as improved control of atrial arrhythmias, could lead to improved quality of life in patients with Ebstein malformation.

SUMMARY

Patients with congenital heart disease require lifelong surveillance. The number of adults living with congenital heart disease continues to grow, in part because of advances in the diagnosis and treatment of congenital heart lesions.^{1,2} There are more than 1 million adults with congenital heart disease in the United States; this population grows by approximately 5% each year.^{3,4}

The challenges of caring for adults with congenital heart disease were underscored in the medical literature by Dr. Joseph Perloff beginning in the 1970s, when he described the pediatric congenital cardiac patient becoming a postoperative adult.⁵ However, it was not until 1990 at the 22nd Bethesda Conference of the American College of Cardiology (ACC) that the care of adults with congenital heart disease was formally recognized as a subspecialty of cardiology care.⁶ In 2001, the 32nd Bethesda Conference attempted to address the changing profile of adults living with congenital heart disease by developing guidelines for resource allocation.²

There is a paucity of literature related to the surgical care of adults with congenital heart disease. Many patients are considered for additional surgery after initial palliations earlier in life. Other patients present with previously undiscovered congenital heart disease requiring surgical intervention. This chapter discusses the expanding adults with congenital heart disease (ACHD) population and its unique challenges. Important aspects of preoperative evaluation and perioperative management are highlighted, and several of the most common lesions encountered by surgeons caring for adults with congenital heart disease are discussed.

EPIDEMIOLOGY

There are more adults than children living with congenital heart disease, and the population continues to grow. The prevalence of adults with congenital heart disease in Quebec, Canada, was 6.12 per 1000 for the year 2010, which was a 57% increase compared with 2000. This compares with an only 10% increase in the prevalence of children with congenital heart disease during the same time period.⁷ This presents several unique challenges to the health care providers that care for these patients.

In 2001, the 32nd Bethesda Conference developed guidelines for resource allocation and program development directed at adults with congenital heart disease. The model for delivery of care focuses on classification of congenital heart defects into different levels of anatomic complexity ([Box 131-1](#)), with referral to specialized adult congenital disease centers for increasing levels of such classification. More than half of the ACHD population is believed to be at increased risk for sudden cardiac death, need for reoperation, and other severe complications. This report estimated that 15% of the ACHD population have anatomically complex disease and require regular follow-up at a specialized center for adult congenital heart disease, and an additional 38% have moderate anatomic complexity of disease requiring periodic follow-up in a specialized center.² The British Cardiac Society Working Party published a similar document addressing the care for the GUCH (grown-up congenital heart) population.⁸ The consensus of both documents is

BOX 131-1 Adult Congenital Heart Disease Lesions by Severity**SIMPLE COMPLEXITY**

- Isolated congenital aortic valve disease
- Isolated congenital mitral valve disease (except parachute valve, cleft leaflet)
- Isolated patent foramen ovale or small atrial septal defect
- Isolated small ventricular septal defect (no associated lesions)
- Mild pulmonic stenosis
- Previously ligated or occluded ductus arteriosus
- Repaired secundum or sinus venosus defect without residua
- Repaired ventricular septal defect without residua

MODERATE COMPLEXITY

- Aortic to left ventricular fistula
- Anomalous pulmonary venous drainage, partial or total
- Atrioventricular canal defects (partial or complete)
- Coarctation of the aorta
- Ebstein anomaly
- Infundibular right ventricular outflow obstruction of significance
- Ostium primum atrial septal defect
- Patent ductus arteriosus (not closed)
- Pulmonary valve regurgitation (moderate to severe)
- Pulmonic valve stenosis (moderate to severe)
- Sinus of Valsalva fistula/aneurysm
- Sinus venosus defect
- Subvalvar or supravalvar aortic stenosis (except hypertrophic cardiomyopathy)
- Tetralogy of Fallot
- Ventricular septal defect with
 - Absent valve or valves
 - Aortic regurgitation
 - Coarctation of the aorta
 - Mitral disease
 - Right ventricular outflow tract obstruction
 - Straddling tricuspid/mitral valve
 - Subaortic stenosis

SEVERE COMPLEXITY

- Conduits, valved or nonvalved
- Cyanotic congenital heart (all forms)
- Double-outlet ventricle
- Eisenmenger syndrome
- Fontan procedure
- Mitral atresia
- Single ventricle (also called double inlet or outlet, common, or primitive)
- Pulmonary atresia (all forms)
- Pulmonary vascular obstructive diseases
- Transposition of the great arteries
- Tricuspid atresia
- Truncus arteriosus/hemitruncus
- Other abnormalities of atrioventricular or ventriculoarterial connection not included above (e.g., crisscross heart, isomerism, heterotaxy syndromes, ventricular inversion)

that all patients (with the exception of those with simple heart lesions) should receive lifelong specialized ACHD care.

STRUCTURED ACHD PROGRAMS

Over the past decade, there has been an increase in the number of centers with specialized multidisciplinary teams committed to the lifelong care of ACHD patients. Many challenges are involved in creating and maintaining a successful team of specialized ACHD providers. Health care providers who specialize in the care of these patients have various levels of experience in ACHD diagnosis and management. Although they are committed to the care of their patients, they may not have had the benefit of training in this subspecialty.⁹ Programs that specialize in ACHD care excel in multidisciplinary collaboration with specialists in not only congenital cardiac disease but also reproductive and obstetric care, nephrology, hepatology, hematology, pulmonary, rheumatology, psychiatric support, palliative care, and transition education. From a cardiac perspective, it is essential to have experienced clinicians with expertise in imaging, electrophysiology, interventional catheterization, congenital cardiac surgery, cardiac anesthesia, critical care, advanced heart failure management, and transplant medicine. The organizational structure should be regionally coordinated, so that regional centers caring for adults with congenital heart disease can easily consult and refer to the specialized programs.¹⁰

Lapse in medical care in adults with congenital heart disease results in adverse outcomes. In a study of 158 adult patients referred to one ACHD center, lapse of medical care, defined as an interval of more than 2 years, occurred for 99 patients (63%). The median duration of lapse of care was 10 years. Patients with lapse of care were 3.1 times more likely to require urgent cardiac interventions ($P = 0.003$).¹¹ In a multicenter study of 922 patients at 12 ACHD centers, 42% experienced a gap in cardiology care that lasted longer than 3 years, and 8% had a gap longer than a decade. The mean age at the first gap was 19.9 years. The most common reasons for gaps included feeling well, being unaware that follow-up was required, and complete absence from medical care. Disease complexity was predictive of a gap in care among 59% of mild, 42% of moderate, and 26% of severe disease patients reporting gaps ($P < 0.0001$).¹²

Emergencies in the ACHD patient are of particular concern. In one multicenter study of hospital admissions of adults with congenital heart disease, 63% of emergent admissions required cooperation with another specialized department.¹³ An additional challenge that faces the ACHD population is lack of insurance coverage. Congenital heart disease patients without private insurance and older than 17 years are at higher risk of being admitted via the emergency room.¹⁴

A critical volume of patients is needed to maintain expertise in the various disciplines required in the care of ACHD patients. Adult congenital heart surgery should be performed only by surgeons who are experienced in all aspects of congenital heart surgery.¹⁵ In an analysis of

Adapted from Warnes CA, Liberthson R, Danielson GK, et al: Task force 1: the changing profile of congenital heart disease in adult life. *J Am Coll Cardiol* 37:1170–1175, 2001.

the Nationwide Inpatient Sample, early mortality and length of stay were lower for patients who underwent ACHD procedures performed by surgeons with expertise in congenital heart disease.¹⁶ The choice of location for surgery should depend on not only the surgeon but also the multidisciplinary team's support for management of adult comorbidities. The optimal surgical location may be center dependent. Certain factors place adults with congenital heart disease at higher risk of death when surgery is performed at freestanding pediatric hospitals. These risk factors include older age, male sex, government-sponsored insurance, and greater surgical complexity.¹⁷ Additionally, greater surgical complexity, government-sponsored insurance, DiGeorge syndrome, weekend admissions, and depression result in higher resource use in ACHD surgical admissions.¹⁸ Analysis of the Nationwide Inpatient Sample examining ACHD surgical admissions to adult hospitals identified nonelective admissions, government-sponsored insurance, surgical complexity, heart failure, renal failure, and complications as risk factors for higher resource utilization.¹⁹

SURGICAL INDICATIONS IN ACHD PATIENTS

The ACC and American Heart Association (AHA) have developed guidelines for management of adults with congenital heart disease, which include recommendations for surgical interventions.²⁰ It is important to recognize the decision to proceed with surgery in the ACHD patient is multifactorial. The goals of prolonging survival and improving quality of life are paramount. The use of previously established measures of physical functioning (such as New York Heart Association [NYHA] class) is difficult to assess in the ACHD patient. Many patients, having lived with the sequelae of cardiac disease since birth, do not perceive themselves as "limited" in the setting of markedly diminished objective exercise capacity.²¹ There is a common misconception that surgical palliation of a congenital heart defect in infancy or childhood is "curative." Therefore, by the time that patients are formally evaluated, ventricular dysfunction may be severe and irreversible.²² Despite this, NYHA class of III or higher has been associated with increased operative mortality, major adverse events, and greater length of stay in ACHD patients undergoing surgery.²³

Pediatric surgical risk scoring systems, such as Aristotle or STAT, may offer some prognostic value in ACHD patients but have limitations in their applicability. For example, high-risk surgeries often include procedures primarily done in infants (such as the Norwood operation or interrupted aortic arch repair), and the distribution of procedures in ACHD patients is skewed toward those classified as lower risk. Furthermore, patient comorbidities that may influence surgical outcome in the pediatric population (such as those in the Aristotle Comprehensive Scoring system, including low birth weight, prematurity, and noncardiac congenital anomalies) may not be as applicable in the adult population, whereas diabetes, hypertension, vascular disease, markers of hepatic disease, and NYHA class may be more meaningful.^{24, 25} In a

multicenter study of 2012 ACHD patients requiring surgery from 13 European countries, preoperative cyanosis, arrhythmias, and NYHA class of III or higher were risk factors for hospital mortality.²⁶

A subset of ACHD patients are referred for primary surgical correction. The principle reason for this is late diagnosis, for example, patients with atrial septal defects or aortic coarctation. Patients may also be referred as adults for a condition that was previously considered inoperable, or because they are from a geographic region without local surgical congenital heart expertise, or because they have anatomically complex lesions but balanced systemic and pulmonary blood flows. Patients with unrepaired tetralogy of Fallot and pulmonary atresia have a poor prognosis; survival beyond the fifth decade is rare.²⁷

PREOPERATIVE EVALUATION

The evaluation of an ACHD patient who is being considered for surgery is extensive. It begins with a thorough review of the underlying anatomy and physiology. This must include retrieval of any previous surgical reports, if possible, so that any unusual features or complications are known and can be anticipated. A further understanding of the current cardiac anatomy can be gained by the use of specific imaging modalities. Imaging should not only focus on cardiac function but also examine for any residua of previous surgery that should be addressed. The imager must be aware of the various potential residual sequelae to evaluate for, such as branch pulmonary artery stenosis at the insertion site of previously taken down systemic to pulmonary artery shunts. Three-dimensional echocardiography is particularly useful for understanding valvular morphology and mechanisms that contribute to valvular dysfunction.

Cardiovascular magnetic resonance imaging (CMR) is increasingly used to quantify ventricular volumes, function, and vascular anatomy.^{28,29} Gadolinium-enhanced contrast CMR can also evaluate myocardial viability. Cardiac computed tomography (CT) is an alternative for patients who have contraindications to CMR, and it provides excellent coronary imaging.³⁰

Imaging can also be helpful to determine the anatomic relationships of certain vascular structures, particularly the relationship of the aorta to the sternum (Fig. 131-1). This is particularly important for repeat sternotomy, which may be associated with inadvertent aortic entry. Preoperative duplex ultrasonography of the femoral and iliac arteries and veins shows the status of the patency of these vessels in ACHD patients who have undergone previous interventions. This is essential in the case of those patients who may need urgent peripheral cannulation for cardiopulmonary bypass.

Cardiac catheterization is often required to determine the cardiac hemodynamics and to determine if there are any associated lesions that should be addressed in the catheterization laboratory.³¹ Coronary angiography should be considered based on the presence of risk factors, presence of angina, noninvasive evidence of ischemia, reduced systemic ventricular function, history of myocardial infarction, or for those patients with prior

FIGURE 131-1 ■ Turbo-spin echocardiographic magnetic resonance image in the axial plane demonstrates the ascending aorta (AAo) and right ventricular outflow tract (RVOT) conduit closely adherent to the posterior table of the sternum.

coronary or great artery surgery. This includes adults with transposition of the great arteries who have undergone an arterial switch procedure with coronary translocation.³² There is a consensus that selective coronary angiography should be performed in men older than 40 years who have congenital heart disease and have been referred for surgery and in similar postmenopausal women.^{20,33} As many as 33% of selected ACHD patients may have an asymptomatic coronary artery anomaly that is discovered with coronary angiography; this is an important preoperative finding.³⁴ Exercise capacity should be examined with objective exercise testing.³⁵

An intensive electrophysiologic evaluation of the preoperative ACHD patient is essential. The incidence of arrhythmias is highest in those patients with moderate or severe ACHD complexity. For example, as many as one third of adults with repaired tetralogy of Fallot develop symptomatic atrial tachycardia,³⁶ approximately 10% develop high-grade ventricular arrhythmias,³⁷ and approximately 5% require permanent pacemaker placement for sinus node dysfunction or atrioventricular block. Additionally, an increasing number of adults with repaired tetralogy of Fallot are receiving implantable cardioverter defibrillators for treatment of ventricular tachyarrhythmia.³⁸

The importance of a multisystem approach to the ACHD patient during the preoperative evaluation cannot be overemphasized. In a retrospective analysis of more than 1100 ACHD patients, 9% had moderate or severe renal dysfunction with a reported threefold increase in mortality.³⁹ Lung function can be significantly diminished in the ACHD patient as a result of previous thoracotomy and resultant scoliosis and restrictive lung disease. ACHD patients with cyanosis are at risk for multisystem derangement, including abnormal hematologic indices, coagulopathy, nephropathy, and hepatic dysfunction.⁴⁰ Heart failure should be identified and medical therapies maximized to achieve critical predictors of improved outcomes.¹⁹

ACHD patients and their families should be educated on the potential benefits and possible risks of the surgical procedure. Some adults with congenital heart disease have emotional problems from previous childhood interventions, and their concerns must be addressed preoperatively. Additionally, patients may have a deleterious body image based on previous surgical scars.⁴¹ A dedicated discussion to the options regarding surgical entry, including possible techniques to minimize further scarring, is often helpful.

PERIOPERATIVE MANAGEMENT

The physiology of the ACHD patient is often complex, and an experienced cardiac anesthetist must be responsible for the care of the patient from the preinduction period through the postoperative management. The experienced anesthetist is essential in managing shifts in the vascular resistance of both the systemic and pulmonary circulations, dynamics of intracardiac shunting, and intravascular volume status. Possible harmful hemodynamic effects related to each anesthetic agent must be considered.⁴² For example, spinal anesthesia can result in a reduction in preload and decrease in pulmonary blood flow. It can also result in a drop in the systemic vascular resistance and an increase in pulmonary to systemic shunting, thus worsening hypoxemia. Narcotics may contribute to an acute reduction in systemic vascular resistance during induction.

Coordination of the operating room team in planning and completing successful sternal reentry is essential. Most surgeries performed on ACHD patients are reoperations. Reoperations are associated with a higher risk, particularly in those patients with cyanosis, transposed great arteries (anterior aorta), pulmonary atresia, or poor ventricular function.⁴³ In one report, early mortality for reoperation approached 10% for those ACHD patients who underwent five sternotomies.⁴⁴ The surgeon must recognize the relationships of cardiac structures in the ACHD patient, many of whom have greatly distorted anatomy, particularly when pericardial integrity has been lost as a result of prior surgical interventions. CMR or CT provides excellent visualization of the relationship of cardiac structures to the sternum (see Fig. 131-1).²⁴ In some patients, there is no discernible space between the posterior table of the sternum and a cardiac structure.

Dilated or hypertensive right heart structures are at particular risk during repeat sternotomy. For example, patients with a systemic right ventricle, such as those with complete transposition of the great arteries who have undergone atrial switch repair (Mustard, Senning), have an enlarged anterior right ventricle that may be adherent to the posterior shelf of the sternum. Aneurysmal, thin-walled right ventricular outflow tract patches and dilated ascending aortas may also be closely related to the sternum. The surgeon must be aware of the location of previously placed extracardiac conduits or shunts to avoid possible injury on sternal reentry. Another example includes a massively dilated and thinned-out right atrium in a classic Fontan. It typically crosses the midline and abuts the sternum, and injury to this structure can propagate because

the wall is typically very thin. Additionally, preoperative knowledge of the coronary anatomy is helpful to avoid inadvertent coronary injury. Certain congenital diagnoses have a higher incidence of anomalous coronary origins and courses, such as tetralogy of Fallot, where the left anterior descending coronary artery crosses the right ventricular outflow tract in at least 5% of cases.⁴⁵

Sternal Reentry Protocol

When there is a high possibility of risk to cardiac structures, femoral cannulation may be required. Femoral-to-femoral cardiopulmonary bypass can be established quickly; it allows blood salvage and control of systemic blood flow and pressure and lowers central venous pressure. Venous filling pressure must be controlled above zero to avoid entraining air into the circulation. Once this is established, retrosternal dissection can safely proceed. In some high-risk cases, it is important to dissect out the groin vessels prior to sternotomy.

Management of Bleeding during Resternotomy

Inadvertent injury to cardiac structures can result in life-threatening venous or arterial bleeding. Determining the source of bleeding is critical in the management of hemorrhage. Sources of venous bleeding include the right atrium, right ventricle, innominate vein, and/or pulmonary conduit. Venous bleeding not only causes blood loss but also allows air into the circulation, resulting in paradoxical air embolism. Therefore, positive venous pressure is needed when there is significant venous bleeding to prevent air embolism in those patients with intracardiac shunting. Additional efforts to minimize air entrainment into the circulation include placing the patient in the Trendelenburg position and rotating the table to the patient's left side.

Major arterial bleeding demands immediate control, even if temporary with a clamp, a suture, or direct compression of the bleeding site. Urgent peripheral femoral cannulation and initiation of cardiopulmonary bypass are typically needed. Once bypass is initiated, systemic cooling is performed so that flows can be lowered to control the bleeding site. Low-flow bypass is often sufficient to complete the dissection and repair any aortic injury. If the heart fibrillated, it is crucial to avoid distention, especially if aortic regurgitation is present. Manual compression of the heart may decrease distention until it begins ejecting, and left ventricular vent placement is crucial.

Unique factors that are important in the ACHD surgical patient include the systemic effects of chronic cyanosis, arrhythmia burden, presence of aortopulmonary collaterals, and ventricular dysfunction. Long-standing cyanosis results in intrinsic hemostatic abnormalities, and postoperative hemostasis may be difficult to achieve. ACHD patients with chronic cyanosis often have multiple collateral vessels that are friable and difficult to coagulate. The difficulty in achieving perioperative hemostasis is exacerbated by extensive suture lines and long cardiopulmonary bypass times, which lead to a decrease in

platelet number and activity through consumption coagulopathy and fibrinolysis.

Several strategies to minimize occurrence and effects of postoperative blood loss include the following:

- Preoperative phlebotomy with postoperative autologous blood transfusion
- Preoperative stimulation of bone marrow production with iron repletion in the iron-deficient patient or with erythropoietin
- Extensive and precise hemostasis during sternotomy and dissection
- Ultrafiltration during cardiopulmonary bypass to raise the hematocrit, and administration of a cell saver device
- Administration of antifibrinolytic agents
- Administration of platelets, fresh-frozen plasma, or cryoprecipitate
- Direct application of surgical glue to suture lines

ACHD patients who have depressed ventricular function or abnormal diastolic function and limited cardiac reserve do not tolerate large volume shifts well, and meticulous attempts must be made to achieve postoperative hemostasis. Patients with decreased ventricular function may need mechanical ventricular support (e.g., ventricular assist device, extracorporeal membrane oxygenation) for a limited time in the immediate postoperative period, and appropriate devices should be available during the surgical procedure so that they can be used if a patient fails to wean from cardiopulmonary bypass.

Efforts must be made to provide optimal myocardial protection during the surgery. Almost all ACHD patients are at risk for perioperative myocardial injury by several mechanisms, depending on the underlying physiology. These include washout of cardioplegia as a result of acquired collateral vessels that involve the coronary circulation, increased pulmonary venous return causing ventricular distention, and inadequate myocardial preservation as a result of extensive ventricular hypertrophy.

Strategies to improve myocardial protection include the following:

- More frequent administration of cardioplegia
- Venting of the heart to prevent overdistention
- In selected cases, the use of low-flow hypothermic cardiopulmonary bypass

A low cardiac output state can occur immediately postoperatively for a variety of reasons. Volume management is critical and depends on adequate hemostasis. Many ACHD patients have poorly compliant ventricles, because of either hypertrophy or restrictive ventricular physiology, and this may contribute to a low output state. Postoperative arrhythmias can cause an acute change in the cardiac output. Any arrhythmia must be recognized and treated immediately.

Low systemic perfusion with accompanying low systemic vascular resistance can occur postoperatively as well. It occurs most often in patients with preoperative heart failure and congestion of systemic venous pressure, those with known presurgical liver disease, or in patients with established risk factors for postoperative systemic inflammatory response syndrome (SIRS).

Additional surgical consideration for adult patients with history of long-standing congenital heart disease or

prior congenital heart surgery include propensity for calcification of cardiac structures and patch material, which can alter the surgical treatment. For example, patients with circumferential calcification of patent ductus arteriosus are at risk for fracture and bleeding with simple ligation using the traditional thoracotomy approach, and sternotomy with patch closure through the pulmonary artery may be the preferred approach. Similarly, treatment of a residual patch margin ventricular septal defect is complicated by the presence of calcification, which may prevent simple patch closure and necessitate excision of the calcified portion of the patch. Preoperative imaging must be carefully examined for evidence of calcification in the operative field.

POSTOPERATIVE MANAGEMENT

ACHD surgical care must be performed in a setting with a structured ACHD program that has a multidisciplinary team approach, and this is evident postoperatively. Intensivist and nursing staff should be skilled in working with ACHD patients. The physiology of the lesion often dictates postoperative care. Avoidance of acidosis and maintenance of adequate oxygenation and systemic perfusion are paramount. Postoperative bleeding should be anticipated and controlled. Patients should be reexplored if bleeding is excessive after the first several postoperative hours. Recognition and treatment of arrhythmias must be prompt and successful to avoid hemodynamic instability. Most ACHD patients return from the operating room with both atrial and ventricular temporary pacing wires, which may be used in determining the type of arrhythmia so as to direct therapy. Monitoring lines may be very useful: a transthoracic left atrial line, right atrial line, or pulmonary artery line may be left in the patient. The intensive care outcomes on adults operated on for congenital heart disease are favorable.⁴⁶ The early mortality for 2851 adult congenital patients operated on at the Mayo Clinic from 1993 to 2006 was 2.4%.⁴⁴

Most ACHD patients have residual cardiac issues after repeat surgery, and they must be educated regarding the need for lifelong follow-up. Several organizations are dedicated to improving the care of adults with congenital heart disease. The International Society for Adult Congenital Heart Disease (ISACHD) was founded in 1994 with a mission to promote, maintain, and pursue excellence in the care of adults with congenital heart disease (www.isachd.org). The Adult Congenital Heart Association (ACHA), a national nonprofit organization founded in 1988 by a group of ACHD survivors and their families, is dedicated to improving the quality of life and extending the lives of adults with congenital heart defects. More than 60 specialized clinics for adults with congenital heart disease are listed on the ACHA website (www.achaheart.org).

SPECIFIC LESIONS

To provide successful care to congenital heart patients in adulthood, adult congenital heart surgeons should be

experienced in all aspects of congenital heart disease that are encountered in childhood. Although a thorough review of specific lesions is beyond the scope of this chapter, the management of several more common lesions encountered in adulthood is discussed here. As mentioned earlier, the surgical indications for most congenital heart lesions encountered in adulthood are sparse. However, the ACC/AHA guidelines for the management of adults with congenital heart disease is an excellent summary of the current data.²⁰ Another set of guidelines was published by an international team of experts in 2001.^{33,47}

Atrial Septal Defect

Atrial septal defect (ASD) is one of the most common congenital heart defects. The clinical presentation of left-to-right shunting across an ASD is right ventricular volume overload and pulmonary overcirculation. ASDs that are large may develop during childhood; however, many are not discovered until adult life when patients develop exercise intolerance, atrial arrhythmias, or dyspnea.^{48,49} The indications for closure of an ASD include otherwise unexplained right atrial or right ventricular enlargement, regardless of symptoms. Additionally, patients with ASDs and evidence of established paradoxical embolism, the recurrence of which cannot be otherwise controlled, should be referred for closure, even in the absence of right heart overload. The long-term prognosis after closure for patients younger than 25 years is comparable to that of the general population. Patients corrected at an older age, particularly those older than 40 years, may have decreased long-term survival and experience higher rates of sequelae, including atrial arrhythmias, pulmonary hypertension, and right heart failure.⁴⁹ Therefore, some have questioned the benefit to repairing ASDs in later life, although general consensus and experience suggest improvement in symptomatic patients regardless of age at presentation, extending far into the older adult population.⁵⁰ Among the several types of ASDs, the most common is a secundum ASD—a defect in the region of the fossa ovalis. Surgical repair of secundum ASD has been performed since 1954. Secundum ASDs can often be closed with occluder devices placed percutaneously.⁵¹ However, certain anatomic determinants make percutaneous closure less favorable, including large defects, inadequate tissue rims, and anomalous draining pulmonary veins. Surgical closure is required for primum ASDs, sinus venosus defects (Fig. 131-2), and coronary sinus septal defects.

It is important to recognize the possibility of pulmonary arterial hypertension in the older patient with unrepaired ASD, although it is much more prevalent in patients with large unrepaired ventricular septal defects, complete atrioventricular canal, or patent ductus arteriosus. When pulmonary arterial hypertension is present, pulmonary vascular resistance can increase, compromising potential benefits of ASD closure. Greatest extreme and potential for pathology is noted with reversal of intracardiac shunting and systemic oxygen desaturation, resulting in Eisenmenger physiology. Patients with ASD and Eisenmenger syndrome have a reduced life

FIGURE 131-2 ■ Previously healthy 33-year-old woman with increasing shortness of breath with exertion. **A**, Cine magnetic resonance image in the axial plane demonstrates a sinus venosus defect (*) in the wall that separates the superior vena cava (SVC) and the right upper pulmonary vein (RPV). The arrow indicates the orifice of the RPV through which blood can flow between the left atrium (LA) and the SVC. **B**, Repeat imaging in the same patient performed 1 year after surgery confirms closure of the sinus venosus defect (arrow). Ao, Aorta.

FIGURE 131-3 ■ **A**, Cine magnetic resonance image in the short-axis plane in the same patient as shown in Figure 131-2 demonstrates severe right ventricular (RV) dilation with a preoperative RV end-diastolic volume of 150 mL/m². **B**, Repeat imaging in the same patient performed 1 year after surgical closure demonstrates decreased RV end-diastolic volume to normal at 80 mL/m². LV, Left ventricle.

expectancy.⁵² For patients with ASD and pulmonary arterial hypertension, surgery is not recommended unless the pulmonary vascular resistance is demonstrated to be sufficiently low. In patients with evidence of elevated pulmonary vascular resistance, invasive testing with oxygen or vasodilators such as nitric oxide may be useful in determining appropriateness for surgical candidacy. Patients with ASDs with measured pulmonary vascular resistance greater than 8 Wood units are unlikely to improve with surgery (and repair may shorten survival); current recommendations suggest that when resistance is as high as 4 Wood units, decision regarding surgical repair should include consultation with clinicians with expertise in the assessment and care of pulmonary vascular disease.

The closure of ASDs can sometimes be performed via a transxiphoid or mini-sternotomy approach, conferring a satisfactory cosmetic result without compromising the safety or accuracy of the repair.⁵³ In some select cases, closure of an ASD can be performed safely and effectively via an endoscopic approach, which further minimizes the degree of invasiveness and hastens postoperative recovery.⁵⁴

The operative mortality for surgical closure of ASD should be less than 1%. Most symptomatic adults experience clinical improvement.⁵⁵ In one report,

cardiopulmonary performance in adult patients with surgically repaired ASD was improved at 4 months postoperatively compared with preoperative assessment, and complete restitution to normal was documented 10 years after shunt closure.⁵⁶ The right ventricular volumes begin to decrease immediately after ASD closure (Fig. 131-3) and are significantly reduced as early as 3 months after closure.⁵⁷

The long-term outcomes after ASD closure are generally excellent; however, the benefits are related to the timing of closure. Murphy and colleagues reported that patients repaired before the age of 25 years had 27-year survival rates similar to those of normal controls. However, the 27-year survival rate for patients between the ages of 25 and 40 years of age was 84%, and the survival rate was decreased to 40% for those patients older than 41 years.⁴⁹ The presence of arrhythmias preoperatively is a risk factor for postoperative rhythm disturbance, which occurs in approximately 60% of patients. Additional risk factors for recurrent arrhythmias after closure include age older than 40 years (some series have extended this to older than 60 years) and postoperative onset of atrial fibrillation, atrial flutter, or junctional rhythm.⁵⁸ Therefore, patients referred for ASD closure with existing arrhythmias and patients older than 40 (or

60) years should be considered for ablation at the time of repair.

Sinus Venosus Defect

In a retrospective review of 108 patients at the Mayo Clinic who had undergone sinus venosus defect repair over a 24-year period, symptomatic improvement was noted in 77%. Early mortality was less than 1%. Postoperative mortality was related to older age at repair and poor NYHA class preoperatively. Long-term complications from repair included sinus node dysfunction in 6% and atrial fibrillation in 14%. The presence of atrial fibrillation was related to older age at time of repair.⁵⁹

The choice of surgical technique for repair of sinus venosus defect depends on the patient's particular anatomy, such as size of defect and distance of the anomalous draining pulmonary veins from the superior vena cava (SVC) and right atrium. A single patch repair was used in most of the patients in the Mayo series. A double patch technique consisting of pericardial patch closure of the ASD with rerouting of the pulmonary veins to the left atrium and enlargement of the SVC with a second pericardial patch has been shown in select centers to be associated with less residual vessel stenosis and arrhythmia.⁶⁰ Sinus node injury is prevented by placement of the SVC incision just anterior to the entry of the pulmonary veins into the SVC. The Warden procedure is an alternative technique, which involves division of the SVC above the insertion of the anomalous pulmonary veins with placement of a pericardial patch on the cardiac end of the SVC. The right atrial appendage is opened and anastomosed to the cut end of the SVC.⁶¹

Tetralogy of Fallot

Most adults with tetralogy of Fallot (TOF) underwent repair in childhood. These patients, when referred for surgical consideration in adulthood, often have multiple residual lesions that may need to be surgically addressed, on average 2.9 procedures per patient per reoperation.⁶² TOF is the most common form of cyanotic congenital heart disease. The principal pathologic abnormality involves varying degrees of hypoplasia of the infundibulum, often with anterior, superior, and leftward deviation of the conal septum. As a result, TOF is characterized by right ventricular outflow tract obstruction, right ventricular hypertrophy, a large conoventricular septal defect, and an aorta that overrides the ventricular septum.

Lillehei is attributed with performing the first surgical repair of TOF in 1954; the 30-year survival rate from reoperations for the first 106 patients undergoing surgical repair was 91%.⁶³ The 20-year survival rate of patients treated from the late 1950s to 1972 was approximately 90%.^{64,65} Patients with TOF born prior to the early 1970s were often palliated with systemic artery to pulmonary artery shunts to increase pulmonary blood flow prior to the definitive repair. Most adult survivors with TOF underwent "definitive" repair much later in life than is currently the standard of care, which is younger than 1 year. Definitive surgical repair typically involves patch closure of the ventricular septal defect and an

FIGURE 131-4 ■ Woman, 26 years old, with tetralogy of Fallot with pulmonary atresia who had undergone right ventricular conduit in infancy. Cine magnetic resonance image demonstrates a giant right ventricular (RV) outflow tract aneurysm measuring 13 cm × 8 cm × 8 cm. A large hemispherical thrombus (arrows) occupies the posterior aspect of the aneurysm. LV, Left ventricle. (From Valente A: Adult congenital heart disease. In Libby P, editor: *Essential atlas of cardiovascular disease*, Philadelphia, 2009, Springer/Current Medicine Group.)

infundibular or transannular right ventricular outflow tract patch to relieve the obstruction. However, adults who underwent definitive repair several decades ago were likely to have undergone a generous right ventricular incision and, compared with current technique, less attention to the preservation of the pulmonary valve. Right ventricular outflow tract aneurysms in the ACHD patient are common (Fig. 131-4), and they contribute to right ventricular dysfunction.⁶⁶ Surgical remodeling techniques can be used to reduce the size of the akinetic portion of the right ventricular outflow tract.

Surgical repair of TOF commonly results in anatomic and functional abnormalities in the ACHD population. Common sequelae include right ventricular dilation from pulmonary regurgitation, residual ventricular septal defects (often at the patch margin), tricuspid regurgitation, right ventricular outflow patch aneurysms, and branch pulmonary artery stenoses (commonly at the insertion site of previously taken down systemic to pulmonary artery shunts). The hemodynamic burden of these residua is often well tolerated in childhood. However, the prevalence of exercise intolerance, arrhythmias, heart failure, and death (Fig. 131-5) increase during adulthood.^{67,68} The factors that may contribute to worsening clinic status are demonstrated in Figure 131-6. Gatzoulis and colleagues reported risk factors for sudden death in 793 patients with repaired TOF from six centers

FIGURE 131-5 ■ Long-term survival curve after correction of tetralogy of Fallot. (Adapted from Nollert G, Fischlein T, Bouterwek S, et al: Long-term survival in patients with repair of tetralogy of Fallot: 36-year follow-up of 490 survivors of the first year after surgical repair. *J Am Coll Cardiol* 30[5]:1374–1383, 1997.)

in the United Kingdom and found that older age of repair and QRS duration 180 ms were independent predictors of sudden death. The major hemodynamic abnormality in these patients was the presence of at least moderate pulmonary regurgitation.⁶⁹ Chronic right ventricular volume overload can also dilate the tricuspid valve annulus

with resultant tricuspid valve regurgitation. Progressive tricuspid valve regurgitation can accelerate right ventricular contractile failure and right atrial dilation, which is associated with increased prevalence of atrial arrhythmias.⁶⁹ Adults with repaired TOF commonly have cardiac issues that are not present in childhood, such as progressive aortic root dilation, which is present in at least 15% of adults with repaired TOF. This aortic root dilation may lead to aortic insufficiency.⁷⁰ Left ventricular dysfunction is associated with impaired clinical status and increased risk of sudden cardiac death.^{67,71} Additionally, multiple other organ systems may be affected, and it is not uncommon for ACHD patients with repaired TOF to have renal, hepatic, and pulmonary comorbidities.

In considering an ACHD TOF patient for further surgery, investigation into any heart rhythm disturbances is critical. Programmed ventricular stimulation provides reasonably good predictive information on the risk of future clinical ventricular tachycardia.⁷² A positive study may prompt either catheter ablation of the ventricular tachycardia circuit or implantable cardioverter defibrillator placement. Myocardial fibrosis, as demonstrated by gadolinium-enhanced CMR, has been significantly associated with clinical arrhythmia in adults with repaired TOF.⁷³ Rarely, adults with repaired TOF may have intra-atrial reentrant tachycardia (atrial flutter) or atrial fibrillation from chronic atrial dilation. Definitive elimination can often be achieved with a combined right and left atrial maze procedure, which can be performed during a surgery that is addressing residual hemodynamic issues.

An important question in the care of ACHD patients is the timing of pulmonary valve replacement (PVR) after TOF repair. Multiple factors can contribute to the progression of pulmonary regurgitation, including increasing capacitance of the pulmonary artery, right ventricular dilation, and increased right ventricular compliance.⁷⁴

The decision regarding timing of PVR after TOF repair should involve consideration of the benefit of right ventricular volume reduction prior to irreversible dysfunction and the risk of subsequent valve failure and need for repeat intervention. Although there are few controlled or randomized data suggesting optimal timing of PVR for residual pulmonary regurgitation after repair of TOF, Geva has proposed the following clinical criteria in combination with CMR criteria to use in the decision making of PVR in the asymptomatic patient with repaired TOF.⁷⁵

Repaired TOF with at least 25% pulmonary regurgitation fraction as measured by CMR and two or more of the following criteria:

1. Right ventricular (RV) end-diastolic volume index $> 150 \text{ mL/m}^2$ (z-score > 4); in patients whose body surface area falls outside published normal data, RV/left ventricular (LV) end-diastolic volume ratio > 2
2. RV end-systolic volume index $\geq 80 \text{ mL/m}^2$
3. LV ejection fraction $< 55\%$
4. RV ejection fraction $< 47\%$
5. Large RV outflow tract (RVOT) aneurysm
6. QRS duration $> 140 \text{ ms}$
7. Sustained tachyarrhythmia related to right heart volume load

8. Other hemodynamically significant lesions such as RVOT obstruction with RV systolic pressure $> 2/3$ systemic, severe branch PA stenosis, moderate to severe tricuspid regurgitation, residual atrial or ventricular septal defects with a Qp/Qs > 1.5 , and severe aortic dilation or regurgitation

The operative mortality for PVR after TOF repair is low (about 1%).⁷⁶ However, a continued low risk of death remains after PVR. Of 70 adults with TOF, Therrien reported a survival rate of 92% at 5 years and 86% at 10 years, after PVR.⁷⁷ The longevity of the valve must also be considered, because there is a wide variation in the rates of freedom from valve failure and reoperation, depending on type of valve and patient age.

Patients with TOF who undergo PVR generally have symptomatic improvement with a decrease in right ventricular end-diastolic and end-systolic volumes without significant change in the right ventricular ejection fraction.⁷⁸⁻⁸⁰ Additionally, there is evidence that exercise performance tends to improve after PVR.⁸¹

Ebstein Anomaly

Ebstein anomaly is a congenital malformation of the tricuspid valve and right ventricular sinus. It is a rare disorder, accounting for about 1% of all congenital heart defects.⁸² It was first described in 1866 in a 19-year-old laborer with severe tricuspid regurgitation caused by a severely malformed tricuspid valve. Ebstein anomaly is characterized by several morphologic features, which have varying degrees of severity. The pathogenesis involves failure of delamination of the septal and posterior leaflets of the tricuspid valve, resulting in adherence of the tricuspid valve leaflets to the ventricular myocardium. This results in apical displacement of the functional tricuspid valve annulus and dilation of the "atrialized" portion of the right ventricle. There are varying degrees of hypertrophy and thinning of the right ventricular wall, dilation of the true tricuspid valve annulus, and often fenestrations, redundancy, and tethering of the anterior leaflet. These abnormalities result in varying degrees of tricuspid regurgitation and ventricular dysfunction. Although patients with Ebstein anomaly share common features, no two cases are identical, and there is a great deal of variability in morphology.⁸³ This must be taken into consideration whenever surgical intervention is considered.

The tricuspid valve leaflets are often markedly dysplastic in severe cases. The incomplete fibrous transformation of leaflets results in a downward displacement of the hinge point of the posterior and septal leaflets in a spiral fashion below the true valve annulus. The valve leaflets may be tethered by short chordae and papillary muscles or attached to the myocardium directly or by muscular bands. Fenestrations of the leaflets are common, and chordae may be sparse or absent. In the most severe cases, the septal leaflet is a ridge of fibrous tissue that is directed toward the ventricular apex, the posterior leaflet consists of a few remnants of leaflet tissue near the apex, and the anterior leaflet may be displaced into the right ventricular outflow tract. The anterior leaflet leading edge is particularly important in determining the feasibility of tricuspid valve repair. The leading edge may be free and mobile,

have hyphenated attachments (focal, segmental direct attachments to the underlying myocardium), or have linear direct attachments (entire leading edge attached to the endocardium). Varying degrees of right atrial and ventricular dilation may be present. With severe right ventricular dilation, the ventricular septum is displaced and the left ventricle may be compressed with resultant left ventricular dysfunction.⁸⁴

Associated cardiac lesions include interatrial shunts, patent foramen ovale or ASDs, pulmonary valve stenosis or atresia, and, rarely, ventricular noncompaction. Interatrial shunts are often associated with right-to-left shunting and arterial desaturation. There is a risk of paradoxical embolism and stroke in this setting. Additionally, up to 20% of patients with Ebstein anomaly may have Wolff-Parkinson-White syndrome.⁸⁵ The accessory pathway is typically located along the posterior and septal aspect of the tricuspid ring. As many as half of these patients have more than one accessory pathway.

Ebstein anomaly of the left-sided atrioventricular valve is commonly seen in patients with physiologically corrected transposition of the great arteries. The systemic (morphologically tricuspid) atrioventricular valve is associated with the left-sided systemic morphologic right ventricle. The nature of the displacement of this valve is similar to right-sided Ebstein anomaly, but the anterior leaflet is often smaller. The functional right ventricle and tricuspid valve annulus are very rarely severely dilated.

The diagnosis of Ebstein anomaly is confirmed by two-dimensional echocardiography with the septal leaflet at the crux of the heart demonstrating apical displacement of 0.8 cm/m² or greater. Three-dimensional echocardiography can be particularly helpful in examining the morphology of the tricuspid valve leaflets (Fig. 131-7). CMR is useful for determining ventricular volumes and function, as well as visualization of the position of the tricuspid valve⁸⁶ (Fig. 131-8). The technique of delayed enhancement CMR can identify ventricular fibrosis⁸⁷ in these patients, which has been reported in both right and left ventricular myocardium of patients with Ebstein anomaly.

Patients with mild Ebstein anomaly may live normal life spans, and asymptomatic patients without right-to-left shunting or significant cardiomegaly may be managed medically and may not require surgical intervention. However, many adults living with congenital heart disease do not recognize their limited exercise capacity and may not report their limitations. In a study of 21 adults with Ebstein anomaly, exercise capacity was significantly reduced compared with controls (peak oxygen consumption 21.9 ± 5.4 versus 33.6 ± 8.3 mL/kg/min; $P = 0.000001$). All of these adults considered themselves to be in NYHA class I (71%) or class II (29%); however, objective cardiopulmonary stress testing indicated considerable reduction in the exercise performance of this group.⁸⁸

Several factors should promote consideration of surgery. These include increasing symptoms with decreasing exercise tolerance, cyanosis, documented paradoxical embolism, progressive cardiomegaly, right ventricular dilation or dysfunction, and progression of atrial or ventricular arrhythmias. A biventricular repair is usually possible; however, in cases of severe right ventricular

FIGURE 131-7 ■ **A**, Three-dimensional echocardiographic image of Ebstein anomaly in diastole demonstrates the redundant anterior leaflet of the tricuspid valve (arrows) with diminutive septal leaflet. **B**, Three-dimensional echocardiogram in systole illustrates failure of tricuspid valve coaptation (*). dysfunction with preserved left ventricular function, a bidirectional cavopulmonary shunt may be considered.⁸⁹ Cardiac transplantation is a rare option usually reserved for cases with severe left ventricular dysfunction.

Surgical repair most often involves tricuspid valve repair or replacement. Factors that are favorable for a valve repair include a large, mobile anterior leaflet with a free leading edge. The presence of leaflet tethering, presence of tricuspid valve leaflet tissue in the right ventricular outflow tract or direct insertion of the papillary muscle head into the leading edge of the anterior leaflet makes repair more difficult. Leaflets that have extensive hyphenated attachments or linear attachment of the leading edge to the underlying endocardium are not appropriate for repair. The Mayo Clinic authors reported that if more than 50% of the anterior leaflet has failure of delamination, valve replacement is preferred.⁸³

Many modifications have been made to the original valvuloplasty described by Hunter and Lillehei.⁹⁰ The

original repairs created a monocuspid valve, and whereas subsequent adaptations focused on trying to create a two- or three leaflet valve, most recent technical modifications have focused on monocusp creation with “cone” repair. The principle underlying the cone repair is redistribution of redundant anterior and posterior leaflet to re-create a septal leaflet that is attached to the true annulus, along with annular reduction. Compared with conventional repair techniques, cone repair is associated with more significant reduction in tricuspid regurgitation.⁹¹ When the valve cannot be adequately repaired, a bioprosthetic valve is implanted. Care must be taken to avoid damage to the conduction system, and the suture line is deviated away from the atrioventricular node and membranous septum. The suture line may be deviated cephalad to the tricuspid valve annulus to avoid injury to the right coronary artery.

Considerations should also include closure of any interatrial communications, correction of other associated

anomalies (e.g., pulmonary stenosis), possible plication of the atrialized portion of the right ventricle, and right atrial reduction. A right-sided maze procedure is usually performed, with or without cryoablation of the right atrial isthmus. A left-sided maze is completed in the setting of left atrial enlargement or atrial fibrillation. Occasionally, surgical treatment of accessory conduction pathways is performed. Patients with Ebstein anomaly and arrhythmia show substantial improvement after surgical intervention; however, arrhythmias are not totally abolished. In a study of 45 adults with preoperative arrhythmias who had undergone Ebstein surgery, 39% of the surviving cohort continued to have arrhythmias.⁹²

The largest experience of surgical outcomes in patients with Ebstein anomaly has been reported from the Mayo Clinic. The mean age at the time of initial operation at the Mayo Clinic was 24 years, and 26.5% of the patients had undergone a prior cardiac procedure. Late survival was 84.7% at 10 years and 71.2% at 20 years. Risk factors for poor outcome included right and/or left ventricular systolic dysfunction, increased hemoglobin levels, male sex, hypoplastic pulmonary arteries, and right ventricular outflow tract obstruction.⁹³ Hospitalizations were common even after surgical intervention, with the arrhythmias being the most common admitting diagnosis ($\approx 39\%$). One third of patients continued to report fatigue and shortness of breath.⁹⁴

Single-Ventricle Physiology and Fontan Surgery

Univentricular hearts are rare congenital anomalies, comprising approximately 1% of all congenital heart defects at birth.⁹⁵ The prognosis without surgical intervention in childhood is poor, although, in rare cases, patients with well-balanced circulations survive with reasonable functional capacity into adulthood.⁹⁶

The physiology in infancy depends on several factors, including obstruction to ventricular inflow and outflow, flow across the interatrial septum, systemic and pulmonary venous return, and atrioventricular valve regurgitation. Surgical repair in childhood often involves several staged procedures. An initial palliation with a shunt may be performed, with the ultimate goal of a Fontan physiology.

The Fontan operation was developed in 1971 for palliation of tricuspid valve atresia.⁹⁷ Since that time, several modifications have been performed with the goal of directing systemic venous return directly to the pulmonary arteries without an interposing ventricle. The classic Fontan operation consisted of a valved conduit between the right atrium and main pulmonary artery.⁹⁷ Many of the current adults with single-ventricle physiology have a modified classic Fontan, which involves a direct anastomosis of the right atrium to the pulmonary artery. The next major modification, often referred to as a lateral tunnel, involved creation of an end-to-side anastomosis of the SVC to the undivided right pulmonary artery with an intra-atrial tunnel completed with a patch that tunnels the inferior vena caval blood through the tunnel to the transected SVC.⁹⁸ More recently, extracardiac conduits have been performed.⁹⁹

At the time of Fontan surgery, an ASD may be created in the baffle to “fenestrate” the baffle to allow some right-to-left shunting in the case of elevated systemic venous pressure.¹⁰⁰ This fenestration can often be closed percutaneously later in life to eliminate this residual cause for cyanosis.¹⁰¹ In an analysis of 261 patients with Fontan physiology with a mean age at follow-up of 25 years, actuarial event-free survival rates were 74.8% at 10 years, 68.3% at 20 years, and 53.6% at 25 years. The causes of death were determined to be thromboembolic, heart failure related, and sudden death.¹⁰²

The potential complications that arise in the adult patient with previous Fontan surgery are multiple. Patients with the “older style” Fontans are particularly at risk for right atrial dilation (Fig. 131-9) with thrombus formation and atrial arrhythmias.¹⁰³ These two problems may lead to diminished cardiac output, reduced exercise capacity, and diminished quality of life. The strategy of Fontan conversion was introduced in the early 1990s in an effort to improve outcomes of adult survivors of atrio-pulmonary Fontan procedures.¹⁰⁴ The addition of intra-operative ablation has decreased arrhythmia recurrence¹⁰⁵ with the knowledge that as many as 50% of Fontan patients experience atrial tachycardia by 20 years of follow-up.¹⁰³ The goals of Fontan conversion are to excise a portion of the massively dilated right atrium and eliminate underlying atrial arrhythmias. The Fontan anatomy is reconstructed with a lateral tunnel or extracardiac conduit.¹⁰⁶

Surgical considerations when evaluating a patient for possible Fontan conversion are multiple. These patients usually have undergone several previous sternotomies. They are often in a chronically low cardiac output state, and their output drops further with occurrence of atrial arrhythmias. Multisystem dysfunction involvement is common, including hepatic dysfunction,^{107,108} renal dysfunction, and coagulation abnormalities. High central venous pressure leads to increased bleeding during sternal reentry. The electrophysiologic issues may be multiple, and coordination with an experienced electrophysiologist is crucial to success.¹⁰⁶ Risk factors for death, transplant, or dialysis include ventricular dysfunction, ischemic time greater than 100 minutes, age older than 25 years, more than mild atrioventricular valve regurgitation, cardiopulmonary bypass time greater than 240 minutes, and dominant right or indeterminate ventricular morphology.¹⁰⁶

Deal and colleagues reported their experience with Fontan conversion surgery and 117 patients. Late mortality was 5.9% and attributed to intractable heart failure, coronary artery disease, discontinuation from renal dialysis, injury following motor vehicle accident, and sudden death after sedation administration. The overall arrhythmia recurrence was 12.8% during a mean follow-up of 56 months.¹⁰⁹

SUMMARY

Adult congenital heart surgery is a growing discipline with increasing clinical relevance. Many ACHD patients are at risk for poor outcomes because of the natural progression of uncorrected defects and/or

FIGURE 131-9 ■ A 39-year-old patient with dextrocardia and tricuspid atresia who had undergone a modified classic Fontan operation in his childhood who presented with exercise intolerance and atrial fibrillation. **A**, Cine magnetic resonance image (MRI) in an oblique sagittal plane demonstrates a severely dilated right atrial portion of the Fontan pathway (*). **B**, Cine MRI in an axial plane demonstrates dextrocardia and the dilated Fontan pathway (*) in cross-section. **C**, Cine MRI in the axial plane demonstrates the connection of the classic Fontan pathway to the unobstructed branch pulmonary arteries. **D**, Cine MRI in an oblique sagittal plane illustrates the single ventricular outflow. progression of hemodynamically significant residual lesions. Once the condition is recognized, surgical intervention in the ACHD population can decrease the risk for poor outcomes. This unique population is rapidly growing, and continued development of specialized programs for ACHD care must continue. Surgical subspecialty training and certification in ACHD cardiac surgery has come of age. The success of this field lies in the collaboration of a multidisciplinary team dedicated to life-long care and optimization of outcomes for this population.

ARRHYTHMIA AND PACEMAKER SURGERY IN CONGENITAL HEART DISEASE

Francis Fynn-Thompson • Frank Cecchin

CHAPTER OUTLINE

INDICATIONS AND TECHNIQUES FOR ELECTROPHYSIOLOGIC DEVICE THERAPY IN PEDIATRIC AND CONGENITAL HEART DISEASE

Pacemakers
Cardiac Resynchronization Therapy
Implantable Cardioverter-Defibrillators
Cardiac Sympathetic Denervation

ARRHYTHMIA THERAPY IN ADULTS WITH CONGENITAL HEART DISEASE

Electrophysiologic Substrates in Congenital Heart Disease

Intra-atrial Reentrant Tachycardia (Atrial Flutter)
Atrial Fibrillation

Accessory Pathways

Ventricular Tachycardia
Sinoatrial Node Dysfunction in Patients with Congenital Heart Disease
Atrioventricular Block in Congenital Heart Disease

Pacemaker and Cardioverter-Defibrillator Implantation in Adults with Congenital Heart Disease

SUMMARY

The progress in the management of cardiac arrhythmias related to congenital heart disease (CHD) over the past 40 years mirrors the improvement in outcomes associated with heart disease in children. During the earliest era in the management of CHD, postoperative arrhythmias and heart block were a substantial cause of perioperative mortality. With the advent of direct myocardial pacing and cardiac defibrillation more than 50 years ago, mortality rates dropped substantially. In fact, the earliest history of pacing dates back to the repair of CHD. In 1958, Brockman and colleagues¹ were the first to report the use of a myocardial pacing electrode after repair of a ventricular septal defect. Subsequent advances in arrhythmia detection and therapy coupled with the remarkable progress in pacemaker and defibrillator technology have resulted in a significant evolution in the field of arrhythmia therapy. As a result of the miniaturization of technology and the advances in transvenous techniques, cardiac surgeons have been displaced by the cardiologist in most primary electrophysiologic interventions, both diagnostic and therapeutic. This is especially true in the domain of adult cardiac surgery, where most ablative and pacemaker procedures have been transformed into a transvenous approach performed in the laboratory by cardiologists. Although the same is largely true in treatment of pediatric arrhythmias and arrhythmias associated with CHD,

the inherent size and anatomic constraints in those patients often require more surgical participation in the arrhythmia therapy. There is also a growing population of adults with CHD who have an increasing need for reoperation and arrhythmia surgery as they age.²

INDICATIONS AND TECHNIQUES FOR ELECTROPHYSIOLOGIC DEVICE THERAPY IN PEDIATRIC AND CONGENITAL HEART DISEASE

When pacemakers were first developed in the early 1960s, the implants were all performed by cardiothoracic surgeons using an epicardial approach. Since then, the devices have been adapted to a transvenous approach, and in adults with normal cardiac anatomy, the implants are performed by a cardiologist more than 95% of the time. However, this is not the case for children and CHD patients, for whom congenital cardiac surgeons still perform nearly half of the device procedures. Indications and surgical techniques for the use of electrophysiologic devices in children and CHD patients present the surgeon with unique challenges. A child's chest cavity or vascular dimensions could be too small to host the generator and

leads required, and once implanted, leads could stretch as the child grows, increasing the risk that the leads will later dislodge or fracture. A review of indications and techniques for optimal surgical placement of electrophysiologic devices in the pediatric population is presented.

Pacemakers

The recommendations for permanent pacing in children and patients with CHD are updated regularly. The last update was a practice guideline published in 2012 jointly by the American Heart Association (AHA), the American College of Cardiology Foundation (ACCF), and the Heart Rhythm Society (HRS), and its recommendations are listed in [Box 132-1](#).² A class I indication for pacing exists for atrioventricular (AV) block that persists for more than 7 days after cardiac surgery. (The 7-day cutoff is the starting point, with longer waits for very small or unstable patients who have adequate backup temporary pacing.) The recommendations put special emphasis on age-appropriate heart rates and the presence of CHD or ventricular dysfunction to guide treatment decisions.

Additional indications for permanent pacing may not be as obvious as those listed in the AHA/ACCF/HRS guidelines. If a child with a congenital heart defect requires surgery, it may be prudent to preemptively implant a pulse generator or epicardial leads during the surgery. This can benefit children with preoperative rhythm abnormalities who do not meet the indications listed in [Box 132-1](#), but for whom pacing will be needed postoperatively based on the known natural history of a particular cardiac anomaly or type of surgery. For example, an infant with L-transposition of the great arteries (L-TGA) undergoing ventricular septal defect closure is at risk for complete AV block, even without cardiac surgery, and may benefit from prophylactic epicardial lead placement. Such placement can also assist children undergoing Fontan revision surgery in conjunction with an atrial maze procedure that is likely to result in sinus node dysfunction.³ Careful preoperative screening with 24-hour Holter monitors and electrocardiography (ECG) can help to select the patients who would benefit from prophylactic epicardial lead placement.

BOX 132-1 Recommendations for Permanent Pacing in Children, Adolescents, and Patients with Congenital Heart Disease

CLASS I

1. Advanced second- or third-degree AV block associated with symptomatic bradycardia, ventricular dysfunction, or low cardiac output. (Level of evidence: C)
2. Sinus node dysfunction with correlation of symptoms during age-inappropriate bradycardia. The definition of bradycardia varies with the patient's age and expected heart rate. (Level of evidence: B)
3. Postoperative advanced second- or third-degree AV block that is not expected to resolve or that persists at least 7 days after cardiac surgery. (Level of evidence: B)
4. Congenital third-degree AV block with a wide QRS escape rhythm, complex ventricular ectopy, or ventricular dysfunction. (Level of evidence: B)
5. Congenital third-degree AV block in the infant with a ventricular rate less than 55 beats/min or with congenital heart disease and a ventricular rate less than 70 beats/min. (Level of evidence: C)

CLASS IIA

1. Congenital heart disease and sinus bradycardia for the prevention of recurrent episodes of intra-atrial reentrant tachycardia; sinus node dysfunction may be intrinsic or secondary to antiarrhythmic treatment. (Level of evidence: C)
2. Congenital third-degree AV block beyond the first year of life with an average heart rate less than 50 beats/min, abrupt pauses in ventricular rate that are two or three times the basic cycle length, or associated with symptoms resulting from chronotropic incompetence. (Level of evidence: B)
3. Sinus bradycardia with complex congenital heart disease with a resting heart rate less than 40 beats/min or pauses in ventricular rate longer than 3 seconds. (Level of evidence: C)

4. Congenital heart disease and impaired hemodynamics because of sinus bradycardia or loss of AV synchrony. (Level of evidence: C)
5. Unexplained syncope in the patient with prior congenital heart surgery complicated by transient complete heart block with residual fascicular block after a careful evaluation to exclude other causes of syncope. (Level of evidence: B)

CLASS IIB

1. Transient postoperative third-degree AV block that reverts to sinus rhythm with residual bifascicular block. (Level of evidence: C)
2. Congenital third-degree AV block in asymptomatic children or adolescents with an acceptable rate, a narrow QRS complex, and normal ventricular function. (Level of evidence: B)
3. Asymptomatic sinus bradycardia after biventricular repair of congenital heart disease with a resting heart rate less than 40 beats/min or pauses in ventricular rate longer than 3 seconds. (Level of evidence: C)

CLASS III

1. Transient postoperative AV block with return of normal AV conduction in the otherwise asymptomatic patient. (Level of evidence: B)
2. Asymptomatic bifascicular block with or without first-degree AV block after surgery for congenital heart disease in the absence of prior transient complete AV block. (Level of evidence: C)
3. Asymptomatic type I second-degree AV block. (Level of evidence: C)
4. Asymptomatic sinus bradycardia with the longest relative risk interval less than 3 seconds and a minimum heart rate greater than 40 beats/min. (Level of evidence: C)

Epicardial pacing, the predominant method of pediatric pacing until relatively recently, is now used mainly for patients in whom transvenous pacing is contraindicated or who are undergoing concomitant heart surgery. Some of the contraindications to transvenous pacing include prosthetic tricuspid valves, right-to-left intracardiac shunts, CHD or surgery precluding transvenous access to the cardiac chambers, and small patient size.⁴ Although there are no absolute technical limitations to a transvenous route except in premature infants, venous capacitance and lead failure resulting from growth are important considerations. Although each institution should make individual decisions on the basis of local procedural capabilities and experience, we generally consider transvenous pacemaker implants in children weighing more than 10 kg.

Epicardial leads are available with sutureless (screw-on) or suture-on methods of fixation. Alternatively, a standard transvenous lead can be used in postoperative CHD patients with epicardial scarring. The transvenous lead can be placed using a transmural technique, with the lead passed through the myocardial wall and attached to the endocardium.⁵ The steroid-eluting suture-on epicardial leads are our preferred lead, because the steroid can suppress the subacute threshold rise resulting from tissue inflammatory response. Several studies have shown that these steroid-eluting leads have good intermediate-term performance, with stable acute and chronic pacing and sensing thresholds and longevity similar to transvenous leads.⁶⁻⁹ However, screw-on leads may be preferable for patients who have undergone prior heart surgery, as the depth of scarring can hinder suture-on techniques.

Bipolar pacing is particularly advantageous in patients with abdominal muscle stimulation, those at risk for phrenic nerve stimulation, and those with oversensing problems. Bipolar steroid-eluting suture-on epicardial leads are available, or two unipolar sutureless leads can be joined together into a bipolar pulse generator.

The surgical access can be from a midline sternotomy, a left thoracotomy, or a subxiphoid approach or via video-assisted thoracoscopy.¹⁰ Each method has advantages, but the aim is to allow implantation of the proper number of leads in an individual patient. Finding an optimal site for maintenance of acceptable long-term pacing and sensing thresholds can be difficult because of bleeding, limited myocardial access, myocardial scarring, and pericardial adhesions. In patients with prior extensive right atrial (RA) surgery, left atrial pacing sites and the Bachmann bundle in general have better chronic pacing and sensing thresholds than do right lateral or anterior atrial sites.¹¹ A left thoracotomy can be used for implantation of left atrial epicardial leads in children with CHD.¹² In small infants, short leads (15-25 cm) should be used because long leads left in the pericardial space can ensnare the heart, as noted in several case reports of cardiac strangulation or constriction of a great vessel by pacing leads.^{13,14}

The site of pacing is being recognized as an important determinant of ventricular performance. The systemic ventricle is the chamber of choice to pace and best if it is performed in an apical location.¹⁵ Annular and high outflow tract locations produce worse dyssynchrony. The

effects of pacing site on ventricular performance depend on baseline ventricular function. If ventricular dysfunction is present, it is better to expand the surgical entry access than to pace at a site known to produce ventricular dysfunction.

Once the leads are placed and tested, the pacemaker is typically set in a subrectus pocket, but in very small infants (<3 kg), the generator and leads can be left in the pleural cavity. Although uncommon, the abdominal-positioned generators can migrate into the pericardium,¹⁶ peritoneum,¹⁷ or pelvic space—a complication most often seen in very small infants.

Cardiac Resynchronization Therapy

Biventricular pacing is a treatment used in patients with symptomatic drug-refractory heart failure secondary to dilated cardiomyopathy and associated interventricular conduction delay or dyssynchrony. The aim of cardiac resynchronization therapy (CRT) treatment is to correct AV asynchrony, nonuniformity of ventricular activation, contraction, and relaxation sequences, while providing sequences that are as homogeneous as possible. The data in children for this therapy consist of retrospective reviews rather than the randomized trials seen in adults.

Indications for CRT are well established for adults with normal cardiac anatomy, but not for children and patients with CHD.^{18,19} The standard adult indication for CRT is a QRS duration of greater than 120 msec, an ejection fraction less than 35%, and class II heart failure. Unfortunately, this combination rarely occurs in children. Although 90% of adults meeting these criteria have left bundle branch block, it is more common in patients with CHD such as tetralogy of Fallot to have right bundle branch block and right ventricular (RV) dysfunction. Thus standard criteria for CRT rarely are applicable in the CHD population. CRT in CHD is thus used mainly in cases of poor ventricular function and increased QRS duration (>120 msec) regardless of the QRS morphology.

Types of CRT available are biventricular, dual site, multisite, and temporary. In biventricular pacing, two distinct ventricles are present, with a pacing lead on each ventricle. If two sites on the same ventricle are paced, then it is called *dual-site pacing*. When the systemic ventricle is a single ventricle, then dyssynchrony can be decreased by pacing two widely separate sites on the same ventricle, a maneuver called *multisided pacing*. For children, temporary CRT has been used to improve cardiac output in the early postoperative setting.^{20,21}

Implantable Cardioverter-Defibrillators

Indications for implantable cardioverter-defibrillator (ICD) implantation are listed in [Box 132-2](#). The majority of ICDs are implanted via the transvenous route, but this might not be possible in small patients or those with anatomic constraints. Because ICD leads are larger and prone to fibrosis at the coils, patient size limitations for a transvenous system are different from those for a pacemaker. We try to limit transvenous ICD implantation to children who weigh more than 30 kg.

BOX 132-2 Recommendations for ICD Therapy in Children, Adolescents, and Patients with Congenital Heart Disease

CLASS I

1. ICD implantation is indicated in the survivor of cardiac arrest after evaluation to define the cause of the event and to exclude any reversible causes. (Level of evidence: B)
 2. ICD implantation is indicated for patients with symptomatic sustained VT in association with congenital heart disease who have undergone hemodynamic and electrophysiologic evaluation.
- Catheter ablation or surgical repair may offer possible alternatives in carefully selected patients. (Level of evidence: C)

CLASS IIA

1. ICD implantation is reasonable for patients with congenital heart disease with recurrent syncope of undetermined origin in the presence of either ventricular dysfunction or inducible ventricular arrhythmias at electrophysiologic study. (Level of evidence: B)

CLASS IIB

1. ICD implantation may be considered for patients with recurrent syncope associated with complex congenital heart disease and advanced systemic ventricular dysfunction when thorough invasive and noninvasive investigations have failed to define a cause. (Level of evidence: C)

CLASS III

1. ICD therapy is not indicated for patients who do not have a reasonable expectation of survival with an

acceptable functional status for at least 1 year, even if they meet ICD implantation criteria specified in the class I, IIA, and IIB recommendations above. (Level of evidence: C)

2. ICD therapy is not indicated for patients with incessant VT or VF. (Level of evidence: C)
3. ICD therapy is not indicated in patients with significant psychiatric illnesses that may be aggravated by device implantation or that may preclude systematic follow-up. (Level of evidence: C)
4. ICD therapy is not indicated for NYHA class IV patients with drug-refractory congestive heart failure who are not candidates for cardiac transplantation or CRT-D. (Level of evidence: C)
5. ICD therapy is not indicated for syncope of undetermined cause in a patient without inducible ventricular tachyarrhythmias and without structural heart disease. (Level of evidence: C)
6. ICD therapy is not indicated when VF or VT is amenable to surgical or catheter ablation (e.g., atrial arrhythmias associated with the Wolff-Parkinson-White syndrome, right or left ventricular outflow tract VT, idiopathic VT, or fascicular VT in the absence of structural heart disease). (Level of evidence: C)
7. ICD therapy is not indicated for patients with ventricular tachyarrhythmias because of a completely reversible disorder in the absence of structural heart disease (e.g., electrolyte imbalance, drugs, or trauma). (Level of evidence: B)

CRT-D, Cardiac resynchronization therapy with defibrillator; *ICD*, implantable cardioverter-defibrillator; *NYHA*, New York Heart Association; *VF*, ventricular fibrillation; *VT*, ventricular tachycardia.

Epicardial patches were once used regularly, but they were prone to breakage, infection, and pericardial restriction. Newer techniques use coils placed in subcutaneous or pericardial positions.²² The implantation can be performed as a hybrid procedure using an epicardial or transvenous sensing lead or as a completely subcutaneous system using a far-field electrogram for sensing. The three coil types currently available for hybrid procedures are the subcutaneous coil, superior vena cava (SVC) coil, and standard transvenous lead. The completely subcutaneous system is best used in patients with large body habitus and normal cardiac situs or those without transvenous access to the heart.²³ In young children, there have been issues of both ventricular oversensing and undersensing in addition to pocket erosion.²⁴

Because of the smaller surface area of the coils and the thoracic structure interference, proper can and lead placement is essential to obtain adequate defibrillation thresholds. To achieve the lowest defibrillation energy requirements, it is best if the center of the ventricular mass is between the coil and the can. The coil should not enter the pacemaker pocket, because this can result in a short circuit and device failure.

The two basic approaches used for nontransvenous ICD implantation are a minimally invasive approach and a full exposure via sternotomy or thoracotomy. The minimally invasive approach is preferred for patients with no prior heart surgery.

In the basic implantation sequence, a bipolar epicardial pacing lead is first placed, followed by a coil in the pericardial or pleural cavity. When a minimally invasive procedure is used, an active fixation transvenous lead is placed blindly into the posterior pericardial space, followed by extension of the screw to hold the coil in a stable position. The pace or sense connector is then capped. Intraoperative fluoroscopy or portable chest radiography is used to confirm proper lead position. If full exposure of the heart is available, a 5-cm SVC coil can be sutured directly in position. In levocardia, the best configuration is a high left lateral lead and right subrectus pocket (Fig. 132-1). Finally, defibrillation testing is performed, and if the defibrillation threshold is inadequate, then a second coil (length, 25 or 5 cm) is placed in a subcutaneous or pericardial location on the opposite side.

Cardiac Sympathetic Denervation

Left cardiac sympathetic denervation (LCSD), also known as *left cervical stellate ganglionectomy*, was first described in 1971.^{24a} Although LCSD is considered a highly effective method of surgical antiadrenergic therapy, its clinical use has been limited to a narrow set of indications. The procedure has been used primarily at a few centers for patients affected by the long QT syndrome (LQTS), and who are suboptimally controlled with standard medical therapy, usually consisting of beta-adrenergic

FIGURE 132-1 ■ Chest radiographs of an infant who underwent a minimally invasive nontransvenous cardioverter-defibrillator implantation. **A**, Anteroposterior view. **B**, Lateral view. Note the use of a standard transvenous lead in the pericardial cavity.

blocking medications. A recent multicenter report on a series of LQTS patients having undergone LCSD documented the efficacy of this intervention.^{24b} It reported on 147 patients having undergone LCSD, with 99% having been symptomatic and 48% having suffered an aborted cardiac arrest before the operation. On a mean follow-up of 7.8 years after LCSD, 46% were asymptomatic and ICD shocks decreased by 95%.

A more recent and emerging indication is in patients with catecholaminergic polymorphic ventricular tachycardia (CPVT), a disorder of abnormal myocardial calcium homeostasis,²⁵ characterized by life-threatening ventricular arrhythmias triggered during states of high sympathetic output. Patients with CPVT typically have structurally and functionally normal hearts and a normal baseline electrocardiogram, including a normal QTc measurement.

The surgical technique used in performing the LCSD varies among centers.²⁴ Li and colleagues²⁶ reported the first small series of LQTS patients undergoing LCSD using the video-assisted thoracoscopic surgery (VATS) approach. We recently reported our experience^{27,28} with 24 young pediatric patients who underwent high left thoracic sympathectomy denervation using VATS, of whom 13 were diagnosed with LQTS, nine had CPVT, and two had idiopathic medically refractory ventricular tachycardia (VT). The LCSD procedure on all patients was performed by means of a left-sided VATS approach. After left lung isolation with a double-lumen endotracheal tube or the use of a bronchial blocker, the patient was positioned in a partial right lateral decubitus position. Three small stab incisions were made in the left side of the chest along the midaxillary line, with one incision at the level of the third intercostal space, one at the fourth, and one at the fifth. The first incision was used for the camera, the second for a grasper (or lung retractor if needed), and the third for the electrocautery hook dissector ([Fig. 132-2B](#)). After identifying the structures in the apex of the posterior chest wall and the heads of the ribs, the pleura was incised medial to the heads of the ribs, and the sympathetic chain was identified from the level of

about T1 to T5 (see [Fig. 132-2A](#)). Using electrocautery, the sympathectomy involved transection of the left sympathetic chain at the level of T1, sparing the superior aspect of the stellate ganglion, and then at T5, as well as transection of the associated lateral nerves of Kuntz between those levels.

No severe complications were related to the procedure. Minor and transient postoperative complications occurred in only three patients. Only one patient experienced recurrent but transient arrhythmia in the immediate postoperative period. Longer-term follow-up was available in 22 of 24 patients at a median follow-up of 28 months (range, 4-131 months). Sixteen (73%) of the 22 patients experienced a marked reduction in their arrhythmia burden, with 12 (55%) becoming completely arrhythmia free after sympathectomy. Six (27%) of the patients were nonresponsive to treatment; each had persistent symptoms at follow-up.

This emerging early experience supports the use of cardiac sympathectomy as an effective adjunctive therapy that may be particularly useful for patients who are refractory or intolerant to medical therapy, as well as for patients who receive excessive ICD shocks. LCSD using VATS provides a minimally invasive approach that appears effective and safe, although longer-term follow-up is still required.

ARRHYTHMIA THERAPY IN ADULTS WITH CONGENITAL HEART DISEASE

The number of adult patients with CHD continues to increase. It is estimated that there are currently 2 more than 1 million adults with CHD in the U.S., more than 100,000 in Canada, and 1.8 million in Europe.^{28a,29} Many of these patients bear the weight of many decades of long-standing alterations in the volume- and pressure-loading conditions that result from their heterogeneous and often palliated anatomic arrangements. Approximately 50% are classified as having moderate or severe disease (e.g., tetralogy of Fallot, Ebstein anomaly,

FIGURE 132-2 ■ High left thoracic sympathectomy. **A**, The parietal pleura is scored with electrocautery at the T5 level, revealing the underlying left sympathetic chain, which runs along the posterior chest wall just medial to the heads of the ribs. **B**, The parietal pleural incision is carried up to the T1 level with electrocautery, and the sympathetic chain is divided at the T1 and the T5 level and then isolated by division of all lateral branches.

single-ventricle palliations). Although arrhythmias can develop with even mild disease, the incidence is highest for patients in the moderate and severe categories. As a result of the substantial and cumulative disease burden, cardiac arrhythmias late in life are a substantial source of morbidity, hospital admissions, and mortality for adults with CHD.²⁹ They exhibit the full spectrum of arrhythmia issues, and their complex management presents challenges that are often considerable and shared equally by cardiologist and cardiac surgeon.

Electrophysiologic Substrates in Congenital Heart Disease

Intra-atrial Reentrant Tachycardia (Atrial Flutter)

The most common mechanism for symptomatic tachycardia in the adult CHD population is macroreentry in atrial muscle.³⁰ The terms *intra-atrial reentrant tachycardia* (IART) and *incisional tachycardia* have become common labels for this arrhythmia, to distinguish it from the typical variety of atrial flutter that occurs in structurally normal hearts.³¹⁻³³ Generally, IART tends to be slower than typical flutter, with atrial rates in the range of 150 to 250 beats per minute. In the setting of a healthy AV node, such rates frequently conduct in a rapid 1:1 atrial-to-ventricular pattern that can result in hypotension, syncope, or possibly cardiac arrest.^{34,35} Even if the ventricular response rate is safely titrated, sustained IART can cause debilitating symptoms in some patients from loss of AV synchrony, and it may contribute to thromboembolic complications³⁶ when the duration is protracted. Usually, IART appears many years after operations that involved an atriotomy or other surgical manipulation of RA tissue. It can follow simple procedures such as closure of an atrial septal defect on occasion, but the incidence is higher among patients with advanced dilation, thickening, and scarring of the right atrium.^{37,38} Other risk factors for IART include concomitant sinus node dysfunction ("tachy-brady" syndrome) and older age at time of heart surgery.³⁹

Thus, IART is a particular problem for older patients who have undergone the Mustard, Senning, or older-style Fontan operations, in which extensive suture lines and long-term hemodynamic stress result in markedly abnormal atrial myocardium. The route of propagation for an IART circuit varies according to the anatomic defect and type of surgical repair.⁴⁰ It is usually restricted to RA tissue (regardless of the surgical destination of this tissue) and is modulated by regions of fibrosis from suture lines or patches, which function in combination with natural conduction barriers (crista terminalis, valve orifices, and the superior and inferior caval orifices) to channel the wave front along a macro-reentrant loop.^{41,42} If a tricuspid valve is present, the isthmus between the valve ring and the inferior vena cava is a common component of such circuits, but when the tricuspid valve is absent or otherwise deformed, the circuits follow less predictable paths that can be deciphered only by formal electrophysiologic mapping. Frequently, multiple IART circuits are present in the same patient.⁴³ Once recognized, IART can be terminated with electrical cardioversion,⁴⁴ overdrive pacing maneuvers,⁴⁴ or administration of certain class I or III antiarrhythmic drugs.

The far more difficult task is prevention of recurrence. Multiple strategies have been developed for IART prevention, all of which can have value in certain patients, but none of which represents a universal solution. If the episodes are infrequent, well tolerated, and recognized promptly, it may be sufficient to rely on periodic cardioversion before embarking on more involved therapy. However, if IART episodes become frequent, cause

significant symptoms, or are associated with atrial thrombus formation, aggressive treatment is indicated. The therapeutic options for IART include (1) antiarrhythmic drugs, (2) pacemaker implantation to correct bradycardia or provide automatic atrial antitachycardia pacing, (3) catheter ablation, and (4) surgical intervention with a modified atrial maze operation. The choice must be tailored to the hemodynamic and electrophysiologic status of the individual patient. Chronic antiarrhythmic drugs are still prescribed in some cases, but the broad experience with pharmacologic therapy for this condition has been discouraging,^{34,45} even when potent agents such as amiodarone are used. Pacemaker implantation may be reasonable for patients with a picture of tachy-brady syndrome.³⁵ Pacemakers with advanced programming features that incorporate atrial tachycardia detection and automatic burst pacing to interrupt reentry may also be beneficial in select cases.^{35,46} Catheter ablation is now used at many centers as an early intervention for IART.⁴⁷ The technique has evolved rapidly since the introduction of three-dimensional mapping for improved circuit localization.^{31,48} When these technologies are combined with good anatomic definition and traditional electrophysiologic mapping maneuvers, short-term success rates of nearly 90% can be achieved.

Unfortunately, later tachycardia recurrence is still disappointingly common. The recurrence risk is particularly high (nearly 40%) among Fontan patients, who tend to have the largest number of IART circuits and the thickest or largest atrial dimensions. Although far from perfect, ablation outcomes for IART are likely to improve with continued experience and even now are far superior to the degree of control obtained with medications alone. Furthermore, even if IART episodes are not eliminated entirely by ablation, the procedure can often provide substantial improvement by reducing the frequency of episodes and eliminating the need for ongoing drug therapy.⁴⁸ If these measures fail to prevent IART, or if the patient is returning to the operating room for hemodynamic reasons, consideration should be given to surgical ablation during an RA maze operation. This procedure is used most often for the Fontan population with the most refractory variety of IART, and it is usually combined with revision of the Fontan connection from an older atriopulmonary anastomosis to a modern cavopulmonary connection in the same setting.⁴⁹

The Fontan operation for patients with a single ventricle results in extensive suture lines and abnormal hemodynamics that predispose patients to atrial tachycardias and sinus node dysfunction. Up to 50% of patients with a single ventricle who have undergone older-style Fontan operations develop atrial tachycardia within a decade of surgery. Fontan conversion has been proposed for patients suffering from a variety of late sequelae, including conduit and vascular obstruction, atrial arrhythmias, protein-losing enteropathy, and thrombotic complications. However, documented benefits have been limited to a small number of centers and over short follow-up periods, compared with the relatively extensive data available on initial Fontan procedures.^{50,51} Fontan conversion can provide symptomatic improvement in patients with late complications associated with this

circulation, including atrial tachycardias.⁵²⁻⁵⁴ Criteria for optimal patient selection and anticipated clinical outcomes remain controversial. Conversion alone does not appear to protect against recurrent atrial tachycardias,⁵⁵⁻⁵⁷ whereas concomitant maze surgery can suppress postoperative tachycardia.⁵⁸⁻⁶⁰ Several different surgical approaches have been reported in this heterogeneous patient population. The most recent series from eight centers that have reported outcomes on 10 or more patients have noted variable conversion failure rates, with an aggregate rate of death or transplantation of 8.4% in follow-up of a total of 203 patients.^{53,54,61-67} Significant long-term morbidities, such as renal failure, thrombotic events, and arrhythmia, have likewise been reported.

At Children's Hospital Boston, 40 patients underwent Fontan conversion between 1990 and 2006, 21 (53%) with and 19 (48%) without concomitant arrhythmia surgery.⁶⁸ Table 132-1 summarizes baseline characteristics and surgical considerations in all patients and according to whether they had arrhythmia surgery. Clinical indications for conversion included surgically correctable anatomic lesions ($n = 28$), thrombi ($n = 4$), intracardiac right-to-left shunting ($n = 4$), and medically refractory atrial tachyarrhythmia ($n = 29$), with 16 patients having more than one indication. Four patients had protein-losing enteropathy. In the 39 patients with preoperative catheterization, the ventricular end-diastolic pressure was 9.8 (1.0-22.0) mm Hg, with four having values greater than 12 mm Hg. Preexisting atrial arrhythmias were present in 29 (73%) patients; 10 had macro-reentrant atrial tachyarrhythmia, and 19 had atrial fibrillation (paroxysmal in 12; persistent in 7). Surgical characteristics are summarized in Table 132-1. Twenty-two patients (55%) had a 4-mm fenestration at the time of conversion. Resection of a large portion of the anterior RA wall was performed on 20 patients (50%). All patients with a biatrial maze procedure had a preoperative history of atrial fibrillation. Of 19 patients with a history of AF, 10 underwent a full maze and four had a limited RA maze procedure. Eighteen patients (45%) had concomitant pacemaker implantation (including six with previously implanted devices), and six additional patients required pacemaker placement postoperatively. Perioperative complications, including bleeding, thrombosis, seizures, and renal dysfunction requiring peritoneal dialysis, were observed (Table 132-2).

Six failed conversions (five perioperative deaths, one transplantation) were seen during follow-up, for an overall rate of 15%. Survival was 84% at 3 years postoperatively. Probability of survival did not differ between the two groups, between operative eras, or by whether an extracardiac conduit or a lateral tunnel revision was performed. Univariate predictors for late postoperative arrhythmia are shown in Table 132-3. Arrhythmia interventions including RA debulking, maze procedure, and pacemaker implantation were associated with reduced risk for late postoperative arrhythmias and lower postoperative atrial tachyarrhythmia severity scores. No independent predictors of improved arrhythmia outcomes were identified.

Our experience, concordant with other reports, suggests that survivors of Fontan conversion experience an

improvement in functional status. However, it is our belief that this cannot be explained by overt hemodynamic improvement, because changes on postoperative catheterizations were often minimal and consistent with the effects of fenestration and, in some patients, simple

relief of conduit obstruction. In patients with preoperative arrhythmia who undergo the maze procedure, decrease in tachycardia occurrence and relief from symptoms is substantial, but it is not universal. In addition, significant morbidities and mortality occur primarily in

the perioperative period and are more frequent in our series than in most other reported series. Finally, other than the unfavorable effect of older age at conversion, strong preoperative and procedural predictors of morbidity and mortality were not identified. In particular, the performance of a maze procedure was not associated with a greater risk, and it provided significant benefit to those patients with preoperative arrhythmia. Overall, our findings suggest that, although electrophysiologic and symptomatic improvement can be obtained with Fontan conversion, it is still unclear whether overall survival is favored by Fontan conversion.

Atrial Fibrillation

The principal hemodynamic derangement and site of surgical scarring in CHD tends to involve right heart structures, so that IART arising from the right atrium is by far the most common form of atrial tachycardia. However, chronic hemodynamic stress is directed toward the left atrium in a subset of CHD patients, and atrial fibrillation can occur as a result. The CHD lesions commonly associated with atrial fibrillation include aortic stenosis, mitral valve deformities, and unrepaired single ventricle.⁶⁹ Management principles are similar to those for atrial fibrillation encountered in other forms of adult heart disease, beginning with medical therapy for anticoagulation and ventricular rate control, followed by electrical or medical cardioversion. As with IART, terminating an isolated atrial fibrillation episode in CHD is not difficult, but prevention of recurrence remains a challenge. Antiarrhythmic drugs can offer long-term protection against recurrence for some patients, but as with IART, pharmacologic therapy has been only marginally successful for this purpose. Pacemaker implantation can reduce atrial fibrillation recurrences in patients with sinus node dysfunction when fibrillation is part of the tachy-brady syndrome. Definitive elimination of atrial fibrillation can be achieved with a combined right and left atrial maze operation, which should be considered if a patient requires surgery to address other hemodynamic issues.⁷⁰

Accessory Pathways

The embryologic milieu responsible for congenital heart defects can have a direct effect on development of the conduction system. Sometimes this takes the form of simple displacement of the AV node and His bundle away from the usual septal position in the Koch triangle,³⁰ but occasionally the malformation results in accessory or duplicated AV connections with the potential for reentrant tachyarrhythmias. The most familiar example involves Ebstein anomaly of the tricuspid valve, which is complicated by Wolff-Parkinson-White syndrome in approximately 20% of cases.⁷¹ The accessory pathways in Ebstein anomaly are typically located along the posterior and septal aspect of the tricuspid ring where the valve leaflets are most abnormal,³² and nearly half of these patients are found to have multiple accessory pathways.^{33,72} The same observations hold true for patients with L-TGA, who not infrequently have Ebstein malformation in association with accessory pathways along their left-side tricuspid valve. Tachycardia events for patients with Ebstein anomaly become increasingly problematic in adolescent and adult years, when atrial dilation increases the likelihood of recurrent atrial flutter or atrial fibrillation with potentially rapid anterograde conduction over the accessory pathways. Definitive therapy with catheter ablation is currently viewed as the standard of care for patients with Ebstein anomaly and Wolff-Parkinson-White syndrome. However, compared with ablation for simple accessory pathways in a structurally normal heart, the short-term success rate appears lower, and the risk of recurrence higher, with Ebstein anomaly.^{37,38}

Ventricular Tachycardia

Serious ventricular arrhythmias are rare among CHD patients during their first decade or two of life, but once adulthood is reached, the potential for VT and sudden death becomes a looming concern in certain cases. Patients at greatest risk for developing VT appear to be

those who have undergone a ventriculotomy or patching for certain types of ventricular septal defects. In this scenario, the mechanism for VT is reminiscent of the macroreentrant circuits described earlier for IART, involving narrow conduction corridors defined by regions of surgical scar^{73,74} in conjunction with natural conduction barriers, such as the rim of a septal defect or the edge of a valve annulus. Less commonly, ventricular arrhythmias can develop independently of direct surgical scarring whenever a long-standing hemodynamic overload causes advanced degrees of ventricle dysfunction or hypertrophy. Examples of CHD lesions that can eventually lead to this myopathic variety of VT include (1) aortic valve disease,^{75,76} (2) L-TGA when the right ventricle has been recruited as the systemic ventricle,⁷⁷ (3) severe Ebstein anomaly, (4) certain forms of single ventricle, (5) Eisenmenger syndrome, and (6) unrepaired tetralogy of Fallot.⁷⁸

The bulk of literature and clinical experience regarding VT in CHD has centered on tetralogy of Fallot. The prevalence of VT after tetralogy repair has been estimated to be between 3% and 14% in several large clinical series.^{46,79-83} Some patients with slow VT may be hemodynamically stable at presentation, but VT tends to be rapid for the majority, causing syncope or cardiac arrest to be the presenting symptom. Although rare cases of abrupt AV block or rapidly conducted IART have been linked to catastrophic outcomes in patients with tetralogy,⁸⁴ sustained VT appears to be the single biggest contributor to the incidence (2% per decade) of sudden cardiac death.^{46,81,85-87}

Predicting VT events in patients with tetralogy has been a topic of intense investigation for nearly 30 years. To date, no perfect risk-stratification scheme has emerged, although several clinical variables with modest prognostic value have been identified, including (1) older age at time of definitive surgery, (2) history of palliative shunts, (3) high-grade ventricular ectopy, (4) inducible VT at electrophysiologic study, (5) abnormal RV hemodynamics, and (6) wide QRS width (180 msec). The correlation between QRS duration and VT^{46,82} is not surprising when one considers that the most dramatic degree of QRS prolongation tends to be seen among tetralogy patients with highly dysfunctional and dilated right ventricles. A recent cohort of 873 patients with tetralogy of Fallot from four large centers identified the following factors to be associated with death and sustained VT: RV mass-to-volume ratio ≥ 0.3 g/mL, left ventricle ejection fraction z-score < -2.0 , history of atrial tachyarrhythmia and elevated RV systolic pressure.^{87a}

When viewed in the aggregate, this long list of variables helps to define a clinical profile for the tetralogy patient at risk, but no single item can be viewed as completely independent, and none provides perfect predictive accuracy. To compensate for lack of specificity, the practical approach to VT risk stratification in older patients with tetralogy usually incorporates attention to symptom status. Certainly, any patient who has survived a cardiac arrest or sustained VT is treated aggressively, usually with an ICD.^{88,89} However, in the absence of a serious clinical event, a careful inquiry for more subtle symptoms

is often required to determine whether additional testing or treatment is needed.

At most centers, tetralogy patients who report concerning symptoms of palpitations, dizziness, or syncope usually undergo invasive evaluation with hemodynamic catheterization and an electrophysiology study. Programmed ventricular stimulation provides reasonably good predictive information on the risk of future clinical VT events.^{90,91} A positive study may prompt implantation of a primary-prevention ICD,⁸⁰ or, if monomorphic VT can be induced and is tolerated long enough to permit mapping, catheter ablation of the VT circuit might be considered.⁹²⁻⁹⁵ An electrophysiology study might also uncover IART as a contributing or confounding factor for a patient's symptoms, which could be addressed with ablation at the same time. Correctable hemodynamic issues could also be identified at catheterization and could shift therapy toward a surgical solution, such as relief of valve regurgitation combined with formal intraoperative VT mapping and ablation.⁹⁶

The proper approach to an entirely asymptomatic adult with repaired tetralogy remains unsettled. Most clinicians rely on a yearly evaluation with history and ECG, supplemented regularly with Holter monitoring or exercise testing to screen for high-grade ventricular ectopy, along with periodic echocardiography or magnetic resonance imaging to monitor the status of the right ventricle. Should nonsustained VT be detected on surveillance monitoring in an asymptomatic patient, or should RV function appear to be deteriorating, opinions still vary widely as to the appropriate response. Some clinicians advocate an electrophysiologic study to refine the arrhythmia risk, some recommend pulmonary valve replacement, some prescribe antiarrhythmic drugs, some implant a primary prevention ICD, and some might refrain from any treatment as long as the patient remains symptom free. Therapy continues to be individualized for asymptomatic patients depending largely on institutional experience and philosophy. With few exceptions,^{46,90} studies have been limited to single-center investigations with limited statistical power. Furthermore, because the event rate for sustained VT and sudden death in patients with CHD is low compared with conditions such as ischemic heart disease, the duration of prospective follow-up necessary to answer questions in the CHD field would probably have to extend beyond 10 years. Now that the population of adults with CHD at risk for VT has reached such a substantial size, the opportunity may finally have arrived for an organized assessment of VT management.

Sinoatrial Node Dysfunction in Patients with Congenital Heart Disease

Developmental defects involving the caval-atrial junction can be associated with atypical anatomy and function for the sinoatrial node. This issue is most relevant to complex forms of heterotaxy syndrome in patients with a single ventricle. In the asplenia variety of heterotaxy, bilateral superior caval veins often exist, each with its own sinoatrial node, which results in an interesting ECG pattern of fluctuation between two discrete P

waves at physiologic rates. Apart from the unusual ECG, the coexistence of two sinus nodes is of minimal clinical consequence. In contrast, patients with the polysplenia type of heterotaxy may lack a true sinus node altogether, which makes atrial depolarization dependent on slower atrial or junctional escape rhythms.⁵⁶ Most patients with this rare condition will ultimately require pacemaker implantation. A more common cause of sinus bradycardia in adults with CHD is surgical trauma to the sinoatrial node or its artery, as can occur during the Mustard, Senning, Glenn, and Fontan operations.^{30,39,97,98} Chronotropic incompetence is poorly tolerated in CHD patients with compromised hemodynamics, especially those with a single ventricle or AV valve regurgitation. The likelihood of a patient developing IART or atrial fibrillation is also increased significantly in this setting.³⁹ Implantation of a single- or dual-chamber pacing system is currently recommended⁹⁹ as a class I indication for any patient with CHD and sinoatrial node dysfunction who has symptoms directly attributable to slow heart rate. Pacemaker implantation is also advised as a class IIb indication for CHD patients with resting rates of 40 beats/min or sinus pauses in excess of 3 seconds, even in the absence of symptoms.

Atrioventricular Block in Congenital Heart Disease

The AV conduction tissues may be congenitally abnormal in terms of both location and function in specific forms of CHD, most notably L-TGA and endocardial cushion defects.¹⁰⁰⁻¹⁰² In the former condition, the AV node and His bundle are displaced in an anterior direction away from the usual position in the Koch triangle, whereas in the latter, the AV node and His bundle are displaced posterior to the Koch triangle. The functional properties of these displaced conduction systems are often abnormal. With L-TGA, it is estimated that 3% to 5% of patients will have complete AV block at birth, and an additional 20% will develop spontaneous complete block by adulthood.^{103,104} Even when intrinsic conduction appears normal, these patients appear to be more susceptible to traumatic AV block during surgical or catheter procedures. Surgical repair of certain forms of CHD can result in direct trauma to the AV conduction tissues. Although improved knowledge of the precise location for the AV node and His bundle in various forms of CHD^{30,61,101,105} has reduced the occurrence, closure of some ventricular septal defects, surgery for left-heart outflow obstruction, and replacement or repair of an AV valve may still be complicated by AV block. Fortunately, in more than half of cases, this injury is a transient affair related to myocardial stretch or edema rather than to the physical severing of the conduction tissues, and AV conduction recovers within 7 days of operation.¹⁰⁶ However, for any patient with postoperative AV block that is not expected to resolve or that persists at least 7 days after cardiac surgery, permanent pacemaker implantation is advised⁹⁹ as a class I indication. A pacemaker may be considered by some as a class IIb indication when surgical AV block recovers but the patient is left with permanent bifascicular block.⁸⁴

Pacemaker and Cardioverter-Defibrillator Implantation in Adults with Congenital Heart Disease

Standard transvenous systems are often contraindicated or difficult in CHD patients because of complexities of venous anatomy or because of the presence of significant intracardiac shunting that creates a thromboembolic risk from intravascular leads. Epicardial implantation is often indicated in these circumstances, although the surgery is more involved, and long-term lead performance may be inferior to transvenous systems. Epicardial lead placement in an older patient with CHD who has undergone multiple prior cardiac operations presents the surgeon with a highly scarred mediastinum; dissection down to the myocardial surface must be performed carefully and deliberately to uncover sites with good sensing and pacing function. Careful preoperative planning is often critical, and it is imperative for the surgeon to review all the imaging studies available including chest radiographs, angiograms, and echocardiograms. Many older patients also have chest computed tomography images or magnetic resonance images that are particularly helpful in providing a roadmap for the anatomic relationships and ventricular geometry. After reviewing these studies, a surgeon can often tailor the surgical approach to minimize the need for a large reoperative procedure by using a partial lower median sternotomy incision or a carefully placed limited thoracotomy incision.

If a patient with CHD is undergoing cardiac surgery for other hemodynamic reasons and it appears highly likely that epicardial pacing might be needed at some distant date, the surgeon may want to take advantage of wide intraoperative exposure to place leads for future use and tunnel them under either subcostal region for later easy access. Fortunately, 86% of leads placed at the time of cardiac surgery are found to function well when retrieved at a mean of 252 days after the operation.¹⁰⁷ The indications for ICD implantation in CHD patients are still evolving, but in general they follow guidelines that are similar to those for other varieties of adult heart disease. The most common type of CHD that requires ICD implantation is tetralogy of Fallot, followed by L-TGA and left-sided obstructive diseases.^{88,91} The experience with biventricular resynchronization pacing in CHD patients with depressed ventricular function is limited but promising.¹⁰⁸ Clinical studies are currently underway to refine selection criteria and to investigate the clinical merits of RV resynchronization to offset right bundle branch block after surgical closure of ventricular septal defects and tetralogy repair.

Whether a transvenous or an epicardial approach is being considered, careful preprocedural planning is essential for successful pacemaker or ICD implantation in adults with CHD. Some of these patients have anomalies of systemic venous return and the coronary veins. If pacing in the coronary sinus is needed for cardiac resynchronization or any other purpose, anomalies of the coronary sinus need to be considered, including ostial atresia,¹⁰⁹ unroofed coronary sinus, and extreme dilation caused by persistent left SVC. Venous occlusion is a recognized complication of permanent transvenous pacing

FIGURE 132-3 ■ Chest radiograph of an epicardial implantable cardioverter-defibrillator system in an adult in whom a Kawashima-type Fontan operation was performed for heterotaxy and double-outlet right ventricle. **A**, Posteroanterior projection. **B**, Lateral projection. Defibrillation was obtained via two coils placed in the pericardial space. A short (5-cm) coil is present (*large arrow*), typically used in the superior vena cava and now placed in the pericardial space along the right side of the spine. The second long (25-cm) coil (*small arrows*), normally implanted subcutaneously, lies under the heart and then ascends to the right of the spine.

leads.^{110,111} Venous occlusion is therefore common in adult patients with CHD and long-term pacing, who may have multiple leads in place for several decades. If venous access is needed in the setting of a complete venous occlusion, a variety of techniques for recanalization and venous dilation are now available.¹¹²

Transvenous chamber access can be an issue if complicated atrial baffling has been used to redirect venous return. One major challenge in this regard occurs when ventricular pacing is needed after a Fontan repair. An epicardial approach is used in most of these cases, but successful transvenous ventricular lead implantation after the Fontan operation has now been reported.¹¹³⁻¹¹⁵ Combined challenges of surgical obstacles, chamber access, and unusual ventricular geometry are present in patients with L-TGA after an atrial switch (Mustard or Senning) procedure.¹⁰ Extensive atrial baffling limits sites of atrial capture to small regions in the left atrial appendage (where phrenic nerve stimulation may be hard to avoid), anterior left atrial roof, or SVC to right atrium junction. Baffle obstruction is fairly common in these patients and may require endovascular stent placement before lead placement. In addition, the ventricular lead must be placed in a morphologic left ventricle that is thin and nontrabeculated, which requires close attention to lead-tip fixation and sensing parameters. Intracardiac shunts can lead to embolic stroke via right-to-left shunting or inadvertent lead placement in the systemic circulation.¹¹⁶ Trivial shunts that are predominately left to right are probably not absolute contraindications to transvenous leads, but larger shunts, particularly if right to left, need to be evaluated carefully by angiography or echocardiography before a final decision is made on the route for lead implantation. If transvenous leads are strongly preferred in such cases, shunt closure can be attempted beforehand with interventional techniques such as septal occluders, covered stents, or even surgery.^{117,118} If intracardiac shunting cannot be eliminated satisfactorily, epicardial lead

placement is probably the wisest alternative. Transvenous ICD lead implantation requires a thorough understanding of the ventricular anatomy and chamber positions to anchor the lead tip securely and ensure a suitable vector for defibrillation. When epicardial ICD leads are required, there has been a shift away from traditional patches to novel configurations involving coils (Fig. 132-3) placed in a subcutaneous or pericardial position.¹¹⁹ This can often be accomplished through a limited subxiphoid approach or a left mini-thoracotomy to provide access to the posterior pericardial space. The experience with this approach is limited, but it appears to offer increased flexibility that can accommodate a wide variety of ventricular geometries and heart sizes.

SUMMARY

Despite the evolution of the management of arrhythmias associated with CHD away from cardiac surgeons, definitive surgical arrhythmia therapy still plays an important role, but one that has been redefined in the current era. Given the success of transcatheter approaches to treat most forms of arrhythmias, only a small number of patients will require primary surgical ablation. However, with a growing population of adults with CHD, their specific arrhythmia challenges will necessitate the continued collaboration of cardiologist and cardiac surgeon to provide novel and often hybrid solutions. In the future, advances in device technology, implant techniques, and tissue engineering will further reshape arrhythmia therapy in children. Computer-enhanced telemanipulation and advances in lead technology will facilitate more minimally invasive surgical approaches to epicardial lead placement. In addition, resynchronization and multisite pacing will become more important tools in the management of heart failure associated with congenital heart disease.

QUALITY IMPROVEMENT FOR THE TREATMENT OF PATIENTS WITH PEDIATRIC AND CONGENITAL CARDIAC DISEASE: THE ROLE OF THE CLINICAL DATABASE

Jeffrey P. Jacobs

CHAPTER OUTLINE

NOMENCLATURE

DATABASE

COMPLEXITY STRATIFICATION

DATA VERIFICATION

SUBSPECIALTY COLLABORATION

LONGITUDINAL FOLLOW-UP

QUALITY ASSESSMENT AND QUALITY IMPROVEMENT

SUMMARY: BRIDGING THE GAP FROM ANALYSIS OF OUTCOMES TO IMPROVEMENT OF QUALITY

Although significant progress has been made in the care of patients with pediatric and congenital cardiac disease, complications and death still occur. As a result, optimization of outcomes remains a constant goal. Substantial effort has been devoted to advancing the science of assessing the outcomes and improving the quality of care associated with the treatment of patients with pediatric and congenital cardiac disease.¹⁻²²⁷ The importance of these efforts is supported by the fact that congenital heart defects are the most common birth anomalies, with moderate to severe variants occurring in approximately 6 per 1000 live births.²²⁸

To perform meaningful, multi-institutional outcomes analyses and quality improvement, any database must incorporate the following seven essential elements:

1. A common language and nomenclature*
2. A database with an established uniform core dataset for collection of information[†]

3. A mechanism for evaluating case complexity[‡]
4. A mechanism to ensure and verify the completeness and accuracy of the data collected[§]
5. Collaboration between medical and surgical subspecialties^{||}
6. Standardized protocols for life-long follow-up[¶]
7. Strategies for quality assessment and quality improvement**

The foundation of these seven elements is the use of a common language and nomenclature. The remaining six elements are all dependent on this nomenclature; therefore, quality improvement in the domain of congenital cardiac disease depends on a solid understanding of cardiac morphology and nomenclature.

NOMENCLATURE

Substantial effort has been devoted to the standardization of nomenclature and definitions related to surgery for pediatric and congenital cardiac disease. During the 1990s, both the European Association for Cardio-Thoracic Surgery (EACTS) and the Society of Thoracic Surgeons (STS) created databases to assess the outcomes of congenital cardiac surgery. Beginning in 1998, these two organizations collaborated to create the International Congenital Heart Surgery Nomenclature and Database Project. By 2000, a common nomenclature and a common core minimal dataset were adopted by EACTS and STS and published in the *Annals of Thoracic Surgery*.^{21-54,114} In 2000, the International Nomenclature Committee for Pediatric and Congenital Heart Disease was established. This committee eventually evolved into the International Society for Nomenclature of Paediatric and Congenital Heart Disease (ISNPCHD). By 2005, members of the ISNPCHD cross-mapped the nomenclature of the International Congenital Heart Surgery Nomenclature and Database Project of the EACTS and STS with the European Paediatric Cardiac Code (EPCC) of the Association for European Paediatric Cardiology (AEPC), and therefore created the International Paediatric and Congenital Cardiac Code (IPCCC),¹¹² which is available for free download at <http://www.ipccc.net>.

Most international databases of patients with pediatric and congenital cardiac disease use the IPCCC as their foundation. Two versions of the IPCCC are used in the overwhelming majority of multi-institutional databases throughout the world:

1. The version of the IPCCC derived from the nomenclature of the International Congenital Heart Surgery Nomenclature and Database Project of the EACTS and the STS
2. The version of the IPCCC derived from the nomenclature of the EPCC of the AEPC

These two versions of the IPCCC are also often cited with the following abbreviated short names:

1. EACTS-STS-derived version of the IPCCC
2. AEPC-derived version of the IPCCC

The STS Congenital Heart Surgery Database, the EACTS Congenital Heart Surgery Database, and the Japan Congenital Cardiovascular Surgery Database (JCCVSD) all use the EACTS-STS-derived version of the IPCCC.

The ISNPCHD has published review articles that provide a unified and comprehensive classification, with definitions, for several complex congenital cardiac malformations: the functionally univentricular heart,⁹² hypoplastic left heart syndrome,⁹⁴ discordant atrioventricular connections,⁹⁶ and cardiac structures in the setting of heterotaxy.¹⁰³ These review articles include definitions and a complete listing of the relevant codes and terms in both versions of the IPCCC.

In collaboration with the World Health Organization (WHO), the ISNPCHD is developing the pediatric and congenital cardiac nomenclature that will be used in the eleventh version of the International Classification of Diseases (ICD-11). With a grant funded by the Children's Heart Foundation (www.childrensheartfoundation

.org), the ISNPCHD has also linked images and videos to the IPCCC. These images and videos are acquired from cardiac morphologic specimens and imaging modalities such as echocardiography, angiography, computerized axial tomography, and magnetic resonance imaging, as well as intraoperative images and videos.^{††} These images and videos are available for free download from the internet at (<http://www.IPCCC-awg.NET>). The IPCCC itself is available for free download from the internet at (<http://www.IPCCC.NET>).

The EACTS-STS-derived version of the IPCCC,^{110,112,114} and the common minimum database data set created by the International Congenital Heart Surgery Nomenclature and Database Project,²¹ are currently used by the STS Congenital Heart Surgery Database, the EACTS Congenital Heart Surgery Database, and the JCCVSD. Between 1998 and January 1, 2014 inclusive, this nomenclature and database was used by STS, EACTS, and JCCVSD to analyze the outcomes of 479,000 operations.

DATABASE

The STS Congenital Heart Surgery Database is the largest database in North America cataloging congenital cardiac malformations.^{117,152} It has grown annually since its inception, both in terms of the number of participating centers submitting data and the number of operations analyzed (Figs. 133-1, 133-2, and 133-3). As of January 1, 2014, the STS Congenital Heart Surgery Database currently had 111 participating centers, representing 120 hospitals performing pediatric and congenital cardiac surgery in North America: 117 of an estimated 125 centers from the United States of America that perform pediatric and congenital heart surgery and 3 of 8 centers from Canada that perform pediatric and congenital heart surgery.^{95,174} (The Report of the 2005 STS Congenital Heart Surgery Practice and Manpower Survey, undertaken by the STS Workforce on Congenital Heart Surgery, estimated that 122 centers in the United States of America perform pediatric and congenital heart surgery and 8 centers in Canada perform pediatric and congenital heart surgery.⁹⁵ The Report of the 2010 STS Congenital Heart Surgery Practice and Manpower Survey, undertaken by the STS Workforce on Congenital Heart Surgery, estimated that 125 centers in the United States of America perform pediatric and congenital heart surgery and 8 centers in Canada perform pediatric and congenital heart surgery.¹⁷⁴)

As of January 1, 2014, the STS Congenital Heart Surgery Database therefore contained data from an estimated 93.6% of hospitals (117 of 125) performing pediatric cardiac surgery in the United States. With penetrance of greater than 90%, the data in the STS Congenital Heart Surgery Database is representative of pediatric and congenital heart surgery in the United States. As of January 1, 2014, the number of cumulative total operations in the STS Congenital Heart Surgery Database was

^{††}References 162, 191, 200-202, 209, 213, 218.

FIGURE 133-1 ■ The annual growth of the Society of Thoracic Surgeons Congenital Heart Surgery Database by number of participating centers submitting data. The aggregate report from the Fall 2013 Harvest of the Society of Thoracic Surgeons Congenital Heart Surgery Database¹⁹ includes data from 111 North American Congenital Database Participants representing 120 Congenital Heart Surgery hospitals in North America—117 in the United States and 3 in Canada.

FIGURE 133-2 ■ The annual growth of the Society of Thoracic Surgeons (STS) Congenital Heart Surgery Database by the number of operations per averaged 4-year data collection cycle. The aggregate report from the Fall 2013 Harvest of the STS Congenital Heart Surgery Database¹⁹ includes 136,617 operations performed in the 4-year period of July 1, 2009, to June 30, 2013, inclusive, submitted from 120 hospitals in North America—117 in the United States and 3 in Canada.

FIGURE 133-3 ■ The annual growth of the Society of Thoracic Surgeons (STS) Congenital Heart Surgery Database by the cumulative number of operations over time. As of January 1, 2014, the number of cumulative total operations in the STS Congenital Heart Surgery Database is 292,828. The aggregate report from the Fall 2013 Harvest of the STS Congenital Heart Surgery Database¹⁹ includes 136,617 operations performed in the 4-year period of July 1, 2009, to June 30, 2013, inclusive, submitted from 120 hospitals in North America—117 in the United States and 3 in Canada.

FIGURE 133-4 ■ The annual growth in the European Association for Cardio-Thoracic Surgery (EACTS) Congenital Database by both number of patients and number of operations. As of May 2013, the EACTS Congenital Heart Surgery Database contained 157,772 operations performed in 130,534 patients. As of May, 2013, the EACTS Congenital Heart Surgery Database had 348 centers from 76 countries registered, with 173 active centers from 46 countries submitting data. (Data courtesy Bohdan Maruszewski of the Children's Memorial Health Institute in Warsaw, Poland, Director of the European Association for Cardio-Thoracic Surgery Congenital Database, and Past-President of the European Congenital Heart Surgeons Association.)

292,828.¹⁹ The aggregate Participant Feedback Report from the Fall 2013 Harvest of the STS Congenital Heart Surgery Database includes 136,617 operations performed in the 4-year analytic window of July 1, 2009 to June 30, 2013, inclusive, submitted from 120 hospitals in North America—117 in the United States and 3 in Canada. In collaboration with EACTS, the STS has developed standardized methodology for tracking mortality and morbidity associated with the treatment of patients with congenital and pediatric cardiac disease.^{93,105,212}

The EACTS Congenital Heart Surgery Database is the largest database in Europe dealing with congenital cardiac malformations (Fig. 133-4).^{112,117} As of May 2013, the EACTS Congenital Heart Surgery Database contained 157,772 operations performed in 130,534 patients. As of May 2013, the EACTS Congenital Heart Surgery Database had 348 centers from 76 countries registered, with 173 active centers from 46 countries submitting data.

The JCCVSD has recently been operationalized based on nomenclature and database standards identical to those used by EACTS and STS.¹¹⁷ The JCCVSD began enrolling patients in 2008. By December 2011, more than 100 hospitals were submitting data, and by April 2013, more than 29,000 operations were entered into the JCCVSD, in just under 5 years of data collection (Fig. 133-5). In Japan, it is mandatory for specialists to enroll in this benchmarking project to examine their own performance objectively and to make efforts for continuous improvement. In the future, certification is to be performed solely on the basis of empirical data registered by the project. The developers of the JCCVSD hope to collaborate with their colleagues across Asia to create an Asian Congenital Heart Surgery Database.

In the United Kingdom, the United Kingdom Central Cardiac Audit Database (UKCCAD) uses the AEPC-derived version of the IPCCC as the basis for its national, comprehensive, validated, and benchmark-driven audit of

all pediatric surgical and transcatheter procedures undertaken since 2000.¹⁵² All 13 tertiary centers in the United Kingdom performing cardiac surgery or therapeutic cardiac catheterization in children with congenital cardiac disease submit data to the UKCCAD. Data about mortality are obtained from both results volunteered from the hospital databases, and by independently validated records of deaths obtained by the Office for National Statistics, using the patient's unique National Health Service number, or the general register offices of Scotland and Northern Ireland. Efforts are underway to link the UKCCAD to the EACTS Congenital Heart Surgery Database. Linkage of the UKCCAD to the EACTS Congenital Heart Surgery Database will require use of the cross-map of the AEPC-derived version of the IPCCC (used by the UKCCAD) to the EACTS-STS-derived version of the IPCCC (used by the EACTS, STS, and JCCVSD).

As of January 1, 2014, the STS Congenital Heart Surgery Database contains data from 292,828 operations, the EACTS Congenital Heart Surgery Database contains data from more than 157,772 operations, and the JCCVSD contains data from more than 29,000 operations. Therefore, the combined dataset of the STS Congenital Heart Surgery Database, the EACTS Congenital Heart Surgery Database, and JCCVSD contains data from more than 479,000 operations, all coded with the EACTS-STS-derived version of the IPCCC,^{100,110,112,114} and all coded with identical data specifications.²¹

COMPLEXITY STRATIFICATION

The importance of measuring complexity derives from the fact that analysis of outcomes using raw measurements of mortality, without adjustment for complexity, is inadequate. The mix of cases can vary greatly from

FIGURE 133-5 ■ The initial growth of the Japan Congenital Cardiovascular Surgery Database (JCCVSD). The JCCVSD has recently been operationalized based on identical nomenclature and database standards as that used by the European Association for Cardio-Thoracic Surgery and the Society of Thoracic Surgeons. The JCCVSD began enrolling patients in 2008. By December 2011, more than 100 hospitals were submitting data, and by April 2013, more than 29,000 operations were entered into the JCCVSD, in just under 5 years of data collection. The developers of the JCCVSD hope to collaborate with their colleagues across Asia to create an Asian Congenital Heart Surgery Database. (Data courtesy Arata Murakami, MD, The University of Tokyo, Tokyo, Japan.)

program to program. Without stratification of complexity, the analysis of outcomes will be flawed.^{††}

The analysis of outcomes after surgery requires a reliable method of estimating the risk of adverse events. However, formal risk modeling is challenging for rare operations. Complexity stratification provides an alternative methodology that can facilitate the analysis of outcomes of rare operations. Complexity stratification is a method of analysis in which the data are divided into relatively homogeneous groups (called *strata*). The data are analyzed within each stratum.

Three major multi-institutional efforts have attempted to measure the complexity of congenital cardiac surgical operations:

1. Risk Adjustment in Congenital Heart Surgery-1 methodology (RACHS-1 method)^{56,73,149}
2. Aristotle Basic Complexity Score (ABC Score)^{§§}
3. STS-EACTS Congenital Heart Surgery Mortality Categories (STS-EACTS Mortality Categories, or STAT Mortality Categories)¹⁵⁰

RACHS-1 and the ABC Score were developed at a time when limited multi-institutional clinical data were available and were therefore based largely on subjective probability (i.e., expert opinion). The STAT Mortality Categories are a tool for complexity stratification that was developed from an analysis of 77,294 operations entered into the EACTS Congenital Heart Surgery Database (33,360 operations) and the STS Congenital Heart Surgery Database (43,934 patients) between 2002 and 2007. Procedure-specific mortality rate estimates were calculated using a Bayesian model that adjusted for

small denominators. Operations were sorted by increasing risk and were grouped into five categories (the STS-EACTS Congenital Heart Surgery Mortality Categories) that were designed to be optimal with respect to minimizing within-category variation and maximizing between-category variation.

Table 133-1 compares RACHS-1, the ABC Score, and the STS-EACTS Mortality Categories. Table 133-2 shows the application in the STS Congenital Heart Surgery Database of the STAT Congenital Heart Surgery Mortality Categories.¹⁹⁸ STS has transitioned from the primary use of Aristotle and RACHS-1 to the primary use of the STAT Mortality Categories for three reasons:

1. STAT Score was developed primarily based on objective data, whereas RACHS-1 and Aristotle were developed primarily on subjective probability (i.e., expert opinion).
2. STAT Score allows for classification of more operations than RACHS-1 or Aristotle.
3. STAT Score has a higher c-statistic than RACHS-1 or Aristotle do.

Meaningful evaluation and comparison of outcomes require consideration of both mortality and morbidity, but the latter is much harder to measure. The STAT Mortality Categories provide an empirically based tool for analyzing mortality associated with operations for congenital heart disease.¹⁵⁰ STS has developed the STAT Morbidity Categories²¹⁵ on the basis of major postoperative complications and postoperative length of stay. Both major postoperative complications and postoperative length of stay were used, because models that assume a perfect one-to-one relationship between postoperative complications and postoperative length of stay are not likely to fit the data well. The incorporation of both

TABLE 133-1 **Results of Comparing the STS-EACTS Categories (2009) to the RACHS-1 Categories and the Aristotle Basic Complexity Score***

Method of Modeling Procedures	Model without Patient Covariates	Model with Patient Covariates	Percent of Operations That Can Be Classified
STS-EACTS Congenital Heart Surgery Mortality Categories (2009)	C = 0.778	C = 0.812	99%
RACHS-1 Categories	C = 0.745	C = 0.802	86%
Aristotle Basic Complexity Score	C = 0.687	C = 0.795	94%

*Using an independent validation sample of 27,700 operations performed in 2007 and 2008. In the subset of procedures for which STS-EACTS Category (STAT Mortality Category), RACHS-1 Category, and Aristotle Basic Complexity Score are defined, discrimination was highest for the STS-EACTS categories (C-index = 0.778), followed by RACHS-1 categories (C-index = 0.745), and Aristotle Basic Complexity scores (C-index = 0.687).
RACHS-1, Risk Adjustment in Congenital Heart Surgery-1; *STS-EACTS*, Society of Thoracic Surgeons–European Association for Cardio-Thoracic Surgery.

TABLE 133-2 **Discharge Mortality in Patients in the STS Congenital Heart Surgery Database***

STAT Mortality Category	Total Number of Operations	Discharge Mortality (%)
1	15,441	0.55
2	17,994	1.7
3	8,989	2.6
4	13,375	8.0
5	2,707	18.4

*Patients who underwent surgery between January 1, 2005, and December 31, 2009, inclusive,¹⁹⁸ stratified by STAT Mortality Categories (Society of Thoracic Surgeons–European Association for Cardio-Thoracic Surgery Congenital Heart Surgery Mortality Categories).
STS, Society of Thoracic Surgeons.

major postoperative complications and postoperative length of stay allows for the creation of a much more informative model. The STAT Morbidity Categories provide an empirically based tool for analyzing morbidity associated with operations for congenital heart disease.²¹⁵

DATA VERIFICATION

Collaborative efforts involving EACTS and STS aim to enhance mechanisms to verify the completeness and accuracy of the data in the databases.^{21,126} A combination of three strategies may ultimately be required to allow for optimal verification of data:

- 1. Intrinsic data verification (designed to rectify inconsistencies of data and missing elements of data)
- 2. Site visits with “source data verification” (i.e., verification of the data at the primary source of the data)
- 3. External verification of the data from independent databases or registries (e.g., governmental death registries)

SUBSPECIALTY COLLABORATION

Under the leadership of the MultiSocietal Database Committee for Pediatric and Congenital Heart Disease,¹¹⁰⁻¹¹² further collaborative efforts are ongoing

between congenital and pediatric cardiac surgeons and other subspecialties, including:

- 1. Pediatric cardiac anesthesiologists, via the Congenital Cardiac Anesthesia Society^{105,119,139,207}
- 2. Pediatric cardiac intensivists, via the Pediatric Cardiac Intensive Care Society,¹⁹⁰ and
- 3. Pediatric cardiologists, via the Joint Council on Congenital Heart Disease, the American College of Cardiology (ACC), and the Association for European Paediatric Cardiology.¹¹⁸

Strategies have been developed to link databases together.¹¹¹ By linking different databases, it is possible to capitalize on the strengths and mitigate some of the weaknesses of these databases and therefore perform analyses not possible with either dataset alone. Linked databases have facilitated both comparative effectiveness research^{193,194,219} and longitudinal follow-up.^{145,146,173,214} Under the leadership of the MultiSocietal Database Committee for Pediatric and Congenital Heart Disease,¹¹⁰⁻¹⁴⁰ additional collaborative efforts are ongoing among congenital and pediatric cardiac surgeons and other subspecialties.

LONGITUDINAL FOLLOW-UP

The transformation of the STS Database to a platform for longitudinal follow-up will ultimately result in higher quality of care for all cardiothoracic surgical patients by facilitating longitudinal comparative effectiveness research on a national level.^{127,173,184,214} Several potential strategies will allow longitudinal follow-up with the STS Database, including the development of clinical longitudinal follow-up modules within the STS Database itself, and linking the STS Database to other clinical registries, administrative databases, and national death registries:

- 1. Using probabilistic matching with shared indirect identifiers, the STS Database can be linked to administrative claims databases (such as the CMS Medicare Database^{145,146} and the Pediatric Health Information System [PHIS] database¹¹¹) and become a valuable source of information about long-term

¹¹¹References 109, 164, 189, 193, 194, 210, 219.
¹¹¹References 109, 164, 189, 193, 194, 210, 219.

mortality, rates of rehospitalization, long-term morbidity, and cost.²⁰⁸

2. Using deterministic matching with shared unique direct identifiers, the STS Database can be linked to national death registries, such as the Social Security Death Master File (SSDMF) and the National Death Index (NDI), to verify life status over time.^{127,173,184,214}
3. Through either probabilistic matching or deterministic matching,¹⁸⁴ the STS Database can link to multiple other clinical registries, such as the National Cardiovascular Data Registry (NCDR) of the ACC, to provide enhanced clinical follow-up.
4. The STS Database can develop clinical longitudinal follow-up modules of its own to provide detailed clinical follow-up.^{109,127,173,184,214}

QUALITY ASSESSMENT AND QUALITY IMPROVEMENT

The STS Database is being used increasingly to document variation in outcomes^{182,198} and to measure quality.^{179,186} Funnel plots can be used to demonstrate this variation in outcome and to facilitate the identification of centers that are outliers in performance (Fig. 133-6). Quality improvement initiatives can be initiated in low-performing centers, and best practices can be obtained from high-performing centers.

FIGURE 133-6 ■ Mortality data displayed as a funnel plot for STAT Category 5 operations.¹⁹⁸ The horizontal line depicts aggregate Society of Thoracic Surgeons (STS) mortality before discharge. Curved lines depicting exact 95% binomial prediction limits were overlaid to make a funnel plot. Squares represent the number of cases and mortality before discharge for individual STS Congenital Heart Surgery Database participants (centers). This analysis includes patients undergoing surgery during the 5-year analytic window of 2005 to 2009, inclusive, and includes 70 STS centers in the STS Congenital Heart Surgery Database and 2707 operations. Centers that were identified as outliers represented 18.6% of participating centers (13 of 70); 10% (7 of 70) were “high-performing outliers” and 8.6% (6 out of 70) were “low-performing outliers.” Quality improvement initiatives can be initiated in low-performing centers, and best practices can be obtained from high-performing centers. EACTS, European Association for Cardio-Thoracic Surgery.

STS has collaborated with the Congenital Heart Surgeons’ Society (CHSS) to develop and endorse metrics to assess the quality of care delivered to patients with pediatric and congenital cardiac disease.¹⁸⁶ Box 133-1 and Tables 133-3 and 133-4 present 21 “Quality Measures for Congenital and Pediatric Cardiac Surgery” that were developed and approved by the STS and endorsed by the CHSS. These quality measures are organized according to Donabedian’s Triad of Structure, Process, and Outcome.²²⁹ It is hoped that these quality measures can aid in congenital and pediatric cardiac surgical quality

Text continued on p. 2392

BOX 133-1

Quality Measures for Congenital and Pediatric Cardiac Surgery

1. Participation in a national database for pediatric and congenital heart surgery
2. Multidisciplinary rounds involving multiple members of the health care team
3. Availability of institutional pediatric extracorporeal life support program
4. Surgical volume for pediatric and congenital heart surgery: total programmatic volume and programmatic volume stratified by the five STS-EACTS mortality categories
5. Surgical volume for eight pediatric and congenital heart benchmark operations
6. Multidisciplinary preoperative planning conference to plan pediatric and congenital heart surgery operations
7. Regularly scheduled quality assurance and quality improvement cardiac care conference, to occur no less frequently than once every two months
8. Availability of intraoperative transesophageal echocardiography and epicardial echocardiography
9. Timing of antibiotic administration for pediatric and congenital cardiac surgery patients
10. Selection of appropriate prophylactic antibiotics and weight-appropriate dosage for pediatric and congenital cardiac surgery patients
11. Use of an expanded preprocedural and postprocedural “time-out”
12. Occurrence of new postoperative renal failure requiring dialysis
13. Occurrence of new postoperative neurologic deficit persisting at discharge
14. Occurrence of arrhythmia necessitating permanent pacemaker insertion
15. Occurrence of paralyzed diaphragm (possible phrenic nerve injury)
16. Occurrence of need for postoperative mechanical circulatory support (IABP, VAD, ECMO, or CPS)
17. Occurrence of unplanned reoperation and/or interventional cardiovascular catheterization procedure
18. Operative mortality stratified by the five STS-EACTS mortality levels
19. Operative mortality for eight benchmark operations
20. Index Cardiac Operations free of mortality and major complication
21. Operative survivors free of major complication

CPS, Mechanical CardioPulmonary Support; ECMO, extracorporeal membrane oxygenation; IABP, intra-aortic balloon pump; STS-EACTS, Society of Thoracic Surgeons–European Association for Cardio-Thoracic Surgery; VAD, ventricular assist device.

TABLE 133-3 Definitions of Quality Measures for Congenital and Pediatric Cardiac Surgery

Number	Type	Title of Indicator	Description
S-1	Structure	Participation in a national database for pediatric and congenital heart surgery	Participation in at least one multicenter, standardized data collection and feedback program that provides regularly scheduled reports of the individual center's data relative to national multicenter aggregates and that uses process and outcome measures.
S-2	Structure	Multidisciplinary rounds involving multiple members of the health care team	Occurrence of daily multidisciplinary rounds on pediatric and congenital cardiac surgery patients involving multiple members of the health care team, with recommended participation including but not limited to: cardiac surgery, cardiology, critical care, primary caregiver, family, nurses, pharmacist, and respiratory therapist; involvement of the family is encouraged.
S-3	Structure	Availability of institutional pediatric extracorporeal life support program	Availability of an institutional pediatric extracorporeal life support program for pediatric and congenital cardiac surgery patients; measure is satisfied by the availability of ECMO equipment and support staff, but also applies to ventricular assist devices (including extracorporeal, paracorporeal, and implantable).
S-4	Structure	Surgical volume for pediatric and congenital heart surgery: total programmatic volume and programmatic volume stratified by the five STS-EACTS mortality categories	Surgical volume for pediatric and congenital heart surgery: STS version 2.5: All Index Cardiac Operations* STS version 3.0: Same Surgical volume for pediatric and congenital heart surgery stratified by the five STS-EACTS mortality levels, a multi-institutional validated complexity stratification tool. See O'Brien and colleagues ¹⁵⁰ (Table 1, pp 1140-1146).
S-5	Structure	Surgical volume for eight pediatric and congenital heart benchmark operations	Surgical volume for eight benchmark pediatric and congenital heart operations: These eight benchmark pediatric and congenital heart operations are tracked when they are the primary procedure of an index cardiac operation.* Procedure type VSD repair Abbreviation VSD STS-CHSDB Diagnostic and Procedural Inclusionary and Exclusionary Criteria Procedural inclusionary criteria: 100 = VSD repair, Primary closure 110 = VSD repair, Patch 120 = VSD repair, Device† Diagnostic inclusionary criteria: 71 = VSD, Type 1 (Subarterial) (Supracristal) (Conal septal defect) (Infundibular) 73 = VSD, Type 2 (Perimembranous) (Paramembranous) (Conoventricular) 75 = VSD, Type 3 (Inlet) (AV canal type) 77 = VSD, Type 4 (Muscular) 79 = VSD, Type: Gerbode type (LV-RA communication) Diagnostic exclusionary criteria: 80 = VSD, Multiple Procedural inclusionary criteria: 350 = TOF repair, No ventriculotomy 360 = TOF repair, Ventriculotomy, Nontransanular patch 370 = TOF repair, Ventriculotomy, Transanular patch 380 = TOF repair, RV-PA conduit Diagnostic inclusionary criteria: 290 = TOF 2140 = TOF, Pulmonary stenosis Diagnostic exclusionary criteria: 300 = TOF, AVC (AVSD) 310 = TOF, Absent pulmonary valve 320 = Pulmonary atresia 330 = Pulmonary atresia, IVS 340 = Pulmonary atresia, VSD (Including TOF, PA) 350 = Pulmonary atresia, VSD-MAPCA (pseudotruncus) 360 = MAPCA(s) (major aortopulmonary collateral[s]) (without PA-VSD)

P-1	Process	Multidisciplinary preoperative planning conference to plan pediatric and congenital heart surgery operations *	Norwood	Norwood	Occurrence of a preoperative multidisciplinary planning conference to plan pediatric and congenital heart surgery cases. This conference will involve multiple members of the health care team, with recommended participation including but not limited to: cardiology, cardiac surgery, anesthesia, and critical care. This measure will be coded on a per operation basis. Reporting of compliance will be as a fraction of all cardiac operations.*	Procedural inclusion criteria: 170 = AVC (AVSD) repair, Complete (CAVSD) Diagnostic inclusion criteria: 100 = AVC (AVSD), Complete (CAVSD) Diagnostic exclusion criteria: 110 = AVC (AVSD), Intermediate (transitional) 120 = AVC (AVSD), Partial (incomplete) (PAVSD) (ASD, primum) 300 = TOF, AVC (AVSD) Procedural inclusion criteria: 1110 = Arterial switch operation (ASO) Procedural exclusion criteria: 1120 = Arterial switch operation (ASO) and VSD repair 1123 = Arterial switch procedure + Aortic arch repair 1125 = Arterial switch procedure and VSD repair + Aortic arch repair 1050 = Congenitally corrected TGA repair, Atrial switch and ASO (double switch) Procedural inclusion criteria: 1120 = Arterial switch operation (ASO) and VSD repair Procedural exclusion criteria: 1110 = Arterial switch operation (ASO) 1123 = Arterial switch procedure + Aortic arch repair 1125 = Arterial switch procedure and VSD repair + Aortic arch repair 1050 = Congenitally corrected TGA repair, Atrial switch and ASO (double switch) Procedural inclusion criteria: 950 = Fontan, Atrio-pulmonary connection 960 = Fontan, Atrio-ventricular connection 970 = Fontan, TCPC, Lateral tunnel, Fenestrated 980 = Fontan, TCPC, Lateral tunnel, Nonfenestrated 1000 = Fontan, TCPC, External conduit, Fenestrated 1010 = Fontan, TCPC, External conduit, Nonfenestrated 1030 = Fontan, Other 2340 = Fontan + Atrioventricular valvuloplasty Procedural exclusion criteria: Exclude patients age ≥ 7 years 1025 = Fontan revision or conversion (Re-do Fontan) Procedural inclusion criteria: Primary procedure must be: 230 = Truncus arteriosus repair Procedural exclusion criteria: Exclude any operation if any of the component procedures is: 240 = Valvuloplasty, Truncal valve 2290 = Valvuloplasty converted to valve replacement in the same operation, Truncal valve 250 = Valve replacement, Truncal valve 2220 = Truncus + Interrupted aortic arch repair (IAA) repair Procedural inclusion criteria: 870 = Norwood procedure
	Complete AV canal repair	AVC				
	Arterial switch	ASO				
	Arterial switch + VSD repair	ASO+VSD				
	Fontan	Fontan				
	Truncus repair	Truncus				
	Norwood	Norwood

TABLE 133-3 Definitions of Quality Measures for Congenital and Pediatric Cardiac Surgery—cont'd

Number	Type	Title of Indicator	Description
P-2	Process	Regularly scheduled quality assurance and quality improvement cardiac care conference, to occur no less frequently than once every 2 months	Occurrence of a regularly scheduled quality assurance and quality improvement cardiac care conference to discuss care provided to patients who have undergone pediatric and congenital cardiac surgery operations, including reporting and discussion of all major complications and mortalities, and discussion of opportunities for improvement.
P-3	Process	Availability of intraoperative TEE and epicardial echocardiography	Reporting of compliance will be by reporting the date of occurrence. Annual compliance of 100% equals no fewer than six conferences per year. Availability of intraoperative TEE and appropriate physician and sonographer support for pediatric and congenital cardiac operations. Epicardial echocardiography and appropriate physician and sonographer support should be readily available for those patients in whom TEE is contraindicated or less informative. Availability means presence and availability of equipment and staff.
P-4	Process	Timing of antibiotic administration for pediatric and congenital cardiac surgery patients	This measure will be coded on a per operation basis. Reporting of compliance will be as the fraction of all cardiac operations with availability (as opposed to use) of TEE, epicardial echocardiography, or both.*
P-5	Process	Selection of appropriate prophylactic antibiotics and weight-appropriate dosage for pediatric and congenital cardiac surgery patients	Measure is satisfied for each cardiac operation when there is documentation that the patient has received prophylactic antibiotics within the hour immediately preceding surgical incision (2 hours if receiving vancomycin).*
P-6	Process	Use of an expanded pre-procedural and post-procedural "time-out"	Measure is satisfied for each cardiac operation when there is documentation that the patient received body weight appropriate prophylactic antibiotics as recommended for the operation.*
O-1	Outcome	Occurrence of new postoperative renal failure requiring dialysis	Measure is satisfied for each cardiac operation* when there is documentation of performance and completion of an expanded preprocedural and postprocedural "time-out" that includes the following four elements: 1. The conventional pre-procedural "time-out," which includes identification of patient, operative site, procedure, and history of any allergies. 2. A preprocedural briefing wherein the surgeon shares with all members of the operating room team the essential elements of the operative plan, including diagnosis, planned procedure, outline of essentials of anesthesia and bypass strategies, antibiotic prophylaxis, availability of blood products, anticipated or planned implants or device applications, and anticipated challenges. 3. A postprocedural debriefing wherein the surgeon succinctly reviews with all members of the operating room team the essential elements of the operative plan, identifying both the successful components and the opportunities for improvement. This debriefing should take place <i>before the patient leaves the operating room or its equivalent</i> and may be followed by a more in-depth dialogue involving team members at a later time. (The actual debriefing in the operating room is intentionally and importantly brief, in recognition of the fact that periods of transition may be times of instability or vulnerability for the patient.) 4. A briefing and execution of a hand-off protocol at the time of transfer (arrival) to the intensive care unit at the end of the operation, involving the anesthesiologist, surgeon, physician staff of the intensive care unit (including critical care and cardiology) and nursing. For each surgical admission (index cardiac operation*), code whether the complication occurred during the time interval beginning at admission to operating room and ending 30 days postoperatively or at the time of hospital discharge, whichever is longer. STS version 2.5: 220 = Acute renal failure requiring temporary dialysis 230 = Acute renal failure requiring permanent dialysis STS version 3.0: 230 = Renal failure—acute renal failure requiring dialysis at the time of hospital discharge 223 = Renal failure—acute renal failure requiring temporary dialysis with the need for dialysis not present at hospital discharge 224 = Renal failure—acute renal failure requiring temporary hemofiltration with the need for dialysis not present at hospital discharge

Unless a patient requires dialysis before surgery, renal failure that requires dialysis after surgery constitutes an operative complication, despite the fact that preoperative diminished renal perfusion may have contributed to the development of this complication.

This measure will be reported as percentage of all Index Cardiac Operations. This measure will also be reported stratified by the five STS-EACTS congenital heart surgery mortality categories. (STS is developing Congenital Heart Surgery Morbidity Categories. When these categories are published and available, this metric will be stratified by the STS Congenital Heart Surgery Morbidity Categories instead of the STS Congenital Heart Surgery Mortality Categories.)

O-2 Outcome Occurrence of new postoperative neurologic deficit persisting at discharge

For each surgical admission (index cardiac operation*), code whether the complication occurred during the time interval beginning at admission to operating room and ending 30 days postoperatively or at the time of hospital discharge, whichever is longer.

320 = Neurologic deficit, neurologic deficit persisting at discharge

This measure tracks "new postoperative neurologic deficits" that (1) occur during the time interval beginning at admission to operating room and ending at the time of hospital discharge and (2) persist at discharge.

Such new postoperative neurologic deficits may or may not be related to a stroke. If the new postoperative neurologic deficit is the result of a stroke (that occurs during the time interval beginning at admission to operating room and ending at the time of hospital discharge) and the neurologic deficit persists at discharge, then the following two complications should both be selected:

320 = Neurologic deficit, neurologic deficit persisting at discharge

420 = Stroke

Thus, this complication (320 = neurologic deficit, neurologic deficit persisting at discharge) should be coded when a patient has had a stroke (during the time interval beginning at admission to operating room and ending at the time of hospital discharge) and the neurologic deficit persists at discharge.

This measure does not include a neurologic deficit (which may or may not be related to a stroke) that does not persist at discharge.

NOTE: This complication (320 = Neurologic deficit, neurologic deficit persisting at discharge) should be coded even when the patient has a neurologic deficit that is present before admission to operating room and this neurologic deficit worsens (or a new neurologic deficit develops) during the time interval beginning at admission to operating room and ending at the time of hospital discharge.

This measure will be reported as a percentage of all Index Cardiac Operations. This measure will also be reported stratified by the five STS-EACTS congenital heart surgery mortality categories. (STS is developing congenital heart surgery morbidity categories. When these categories are published and available, this metric will be stratified by the STS Congenital Heart Surgery Morbidity Categories instead of the STS Congenital Heart Surgery Mortality Categories.)

O-3 Outcome Occurrence of arrhythmia necessitating permanent pacemaker insertion

For each surgical admission (Index Cardiac Operation*), code whether the complication occurred during the time interval beginning at admission to operating room and ending 30 days postoperatively or at the time of hospital discharge, whichever is longer.

STS version 2.5:

60 = Postoperative AV block requiring permanent pacemaker

STS version 3.0:

74 = Arrhythmia necessitating pacemaker, permanent pacemaker

This measure will be reported as percentage of all Index Cardiac Operations. This measure will also be reported stratified by the five STS-EACTS congenital heart surgery mortality categories. (STS is developing Congenital Heart Surgery Morbidity Categories. When these categories are published and available, this metric will be stratified by the STS Congenital Heart Surgery Morbidity Categories instead of the STS Congenital Heart Surgery Mortality Categories.)

O-4 Outcome Occurrence of paralyzed diaphragm (possible phrenic nerve injury)

For each surgical admission (index cardiac operation*), code whether the complication occurred during the time interval beginning at admission to operating room and ending 30 days postoperatively or at the time of hospital discharge, whichever is longer.

STS version 2.5:

300 = Phrenic nerve injury/paralyzed diaphragm

STS version 3.0:

300 = Paralyzed diaphragm (possible phrenic nerve injury)

This measure will be reported as percentage of all Index Cardiac Operations. This measure will also be reported stratified by the five STS-EACTS Congenital Heart Surgery Mortality Categories. (STS is developing Congenital Heart Surgery Morbidity Categories. When these categories are published and available, this metric will be stratified by the STS Congenital Heart Surgery Morbidity Categories instead of the STS Congenital Heart Surgery Mortality Categories.)

TABLE 133-3 Definitions of Quality Measures for Congenital and Pediatric Cardiac Surgery—cont'd

Number	Type	Title of Indicator	Description
O-5	Outcome	Occurrence of need for postoperative mechanical circulatory support (IABP, VAD, ECMO, or CPS)	For each surgical admission (index cardiac operation*), code whether the complication occurred during the time interval beginning at admission to operating room and ending 30 days postoperatively or at the time of hospital discharge, whichever is longer. STS version 2.5: 40 = Postoperative mechanical circulatory support (IABP, VAD, ECMO, or CPS) STS version 3.0: 40 = Postoperative or Postprocedural mechanical circulatory support (IABP, VAD, ECMO, or CPS) This complication should be coded even when the patient had preoperative mechanical circulatory support if the patient has mechanical circulatory support postoperatively at any time until 30 days postoperatively or the time of hospital discharge, whichever is longer. This measure will be reported as percentage of all Index Cardiac Operations. This measure will also be reported stratified by the five STS-EACTS congenital heart surgery mortality categories. (STS is developing Congenital Heart Surgery Morbidity Categories. When these categories are published and available, this metric will be stratified by the STS Congenital Heart Surgery Morbidity Categories instead of the STS Congenital Heart Surgery Mortality Categories.)
O-6	Outcome	Occurrence of unplanned reoperation and/or interventional cardiovascular catheterization procedure	For each surgical admission (index cardiac operation*), code whether the complication occurred during the time interval beginning at admission to operating room and ending 30 days postoperatively or at the time of hospital discharge, whichever is longer. STS version 2.5: 20 = Reoperation during this admission (unplanned reoperation) 240 = Bleeding requiring reoperation STS version 3.0: 22 = Unplanned cardiac reoperation during the postoperative or postprocedural time period 24 = Unplanned interventional cardiovascular catheterization procedure during the postoperative or postprocedural time period 26 = Unplanned noncardiac reoperation during the postoperative or postprocedural time period 240 = Bleeding, requiring reoperation <i>n.b. does not include delayed sternal closure</i> This measure will be reported as percentage of all Index Cardiac Operations. This measure will also be reported stratified by the five STS-EACTS congenital heart surgery mortality categories. (STS is developing Congenital Heart Surgery Morbidity Categories. When these categories are published and available, this metric will be stratified by the STS Congenital Heart Surgery Morbidity Categories instead of the STS Congenital Heart Surgery Mortality Categories.) This measure counts all patients who require any additional unplanned cardiac or noncardiac operation and/or interventional cardiovascular catheterization procedure occurring (1) within 30 days after surgery or intervention in or out of the hospital, or (2) after 30 days during the same hospitalization subsequent to the operation or intervention.* The following operations will always be coded as "planned reoperation": (1) delayed sternal closure, (2) ECMO decannulation, (3) VAD decannulation, (4) removal of Broviac catheter. The following operations will always be coded as "Unplanned Reoperation": (1) reoperation for bleeding, (2) reoperation for infection, (3) reoperation for hemodynamic instability, (4) reoperation for initiation of ECMO or VAD, (5) reoperation for residual or recurrent lesion. Operative mortality stratified by the five STS-EACTS mortality levels, a multi-institutional validated complexity stratification tool. See O'Brien and colleagues¹⁵⁰ (Table 1, pp 1140-1146).
O-7	Outcome	Operative mortality stratified by the five STS-EACTS mortality levels	
O-8	Outcome	Operative mortality for eight benchmark operations	Operative mortality for eight benchmark pediatric and congenital heart operations: These eight benchmark pediatric and congenital heart operations are tracked when they are the primary procedure of an index cardiac operation,* and they are listed and described in this table in Measure Number S-5.

O-9 Outcome Index Cardiac Operations free of mortality and major complication

"Index Cardiac Operations free of mortality and major complication" is defined as the percent of pediatric and congenital heart surgery Index Cardiac Operations free of the following: (1) operative mortality, (2) any one or more of the following major complications occurring or diagnosed during the time interval beginning at admission to operating room and ending 30 days postoperatively or at the time of hospital discharge, whichever is longer:

(a) **Renal failure—acute renal failure requiring temporary or permanent dialysis (220, 230, 223, 224)**

- STS version 2.5:
- 220 = Acute renal failure requiring temporary dialysis
- 230 = Acute renal failure requiring permanent dialysis
- STS version 3.0:
- 230 = Renal failure—acute renal failure requiring dialysis at the time of hospital discharge
- 223 = Renal failure—acute renal failure requiring temporary dialysis with the need for dialysis not present at hospital discharge
- 224 = Renal failure—acute renal failure requiring temporary hemofiltration with the need for dialysis not present at hospital discharge

(b) **Neurologic deficit, neurologic deficit persisting at discharge**

- STS version 2.5:
- 320 = Postoperative neurologic deficit persisting at discharge
- STS version 3.0:
- 320 = Neurologic deficit, neurologic deficit persisting at discharge

(c) **Arrhythmia necessitating pacemaker, permanent pacemaker (60, 74)**

- STS version 2.5:
- 60 = Postoperative AV block requiring permanent pacemaker
- STS version 3.0:
- 74 = Arrhythmia necessitating pacemaker, permanent pacemaker

(d) **ECMO/VAD: postoperative mechanical circulatory support (IABP, VAD, ECMO or CPS) (40)**

- STS version 2.5:
- 40 = Postoperative mechanical circulatory support (IABP, VAD, ECMO, or CPS)
- STS version 3.0:
- 40 = Postoperative or postprocedural mechanical circulatory support (IABP, VAD, ECMO, or CPS)

(e) **Paralyzed diaphragm (possible phrenic nerve injury)**

- STS version 2.5:
- 300 = Phrenic nerve injury/paralyzed diaphragm
- STS version 3.0:
- 300 = Paralyzed diaphragm (possible phrenic nerve injury)

(f) **Unplanned reoperation (20, 22, 26 or 240)**

- STS version 2.5:
- 20 = Reoperation during this admission (unplanned reoperation)
- 240 = Bleeding requiring reoperation
- STS version 3.0:
- 22 = Unplanned cardiac reoperation during the postoperative or postprocedural time period, exclusive of reoperation for bleeding
- 24 = Unplanned interventional cardiovascular catheterization procedure during the postoperative or postprocedural time period
- 26 = Unplanned noncardiac reoperation during the postoperative or postprocedural time period
- 240 = Bleeding, requiring reoperation

This measure will be reported as percentage of all Index Cardiac Operations.* This measure will also be reported stratified by the five STS-EACTS congenital heart surgery mortality categories. (STS is developing congenital heart surgery morbidity categories. When these categories are published and available, this metric will be stratified by the STS Congenital Heart Surgery Morbidity Categories instead of the STS Congenital Heart Surgery Mortality Categories.)

Continued

TABLE 133-3 Definitions of Quality Measures for Congenital and Pediatric Cardiac Surgery—cont'd

Number	Type	Title of Indicator	Description
O-10	Outcome	Operative survivors free of major complication	"Operative survivors free of major complication" is defined as the percent of all surviving (live at discharge and 30 days postoperatively) pediatric and congenital heart surgery index operations free of all the following itemized major complications: (a) Renal failure—acute renal failure requiring temporary or permanent dialysis (220, 230, 223, 224) STS version 2.5: 220 = Acute renal failure requiring temporary dialysis 230 = Acute renal failure requiring permanent dialysis STS version 3.0: 230 = Acute renal failure requiring dialysis at the time of hospital discharge 223 = Acute renal failure requiring temporary dialysis with the need for dialysis not present at hospital discharge 224 = Acute renal failure requiring temporary hemofiltration with the need for dialysis not present at hospital discharge (b) Neurologic deficit, neurologic deficit persisting at discharge STS version 2.5: 320 = Postoperative neurologic deficit persisting at discharge STS version 3.0: 320 = Neurologic deficit, neurologic deficit persisting at discharge (c) Arrhythmia necessitating pacemaker, permanent pacemaker (60, 74) STS version 2.5: 60 = Postoperative AV block requiring permanent pacemaker STS version 3.0: 74 = Arrhythmia necessitating pacemaker, permanent pacemaker (d) ECMO/VAD—postoperative mechanical circulatory support (IABP, VAD, ECMO or CPS) (40) STS version 2.5: 40 = Postoperative mechanical circulatory support (IABP, VAD, ECMO, or CPS) STS version 3.0: 40 = Postoperative mechanical circulatory support (IABP, VAD, ECMO, or CPS) (e) Paralyzed diaphragm (possible phrenic nerve injury) STS version 2.5: 300 = Phrenic nerve injury, paralyzed diaphragm STS version 3.0: 300 = Paralyzed diaphragm (possible phrenic nerve injury) (f) Unplanned reoperation (20, 22, 26, or 240) STS version 2.5: 20 = Reoperation during this admission (unplanned reoperation) 240 = Bleeding requiring reoperation STS version 3.0: 22 = Unplanned cardiac reoperation during the postoperative or postprocedural time period, exclusive of reoperation for bleeding 24 = Unplanned interventional cardiovascular catheterization procedure during the postoperative or postprocedural time period 26 = Unplanned non-cardiac reoperation during the postoperative or postprocedural time period 240 = Bleeding, Requiring reoperation This measure will be reported as percentage of all Index Cardiac Operations. This measure will also be reported stratified by the five STS-EACTS congenital heart surgery mortality categories. (STS is developing Congenital Heart Surgery Morbidity Categories. When these categories are published and available, this metric will be stratified by the STS Congenital Heart Surgery Morbidity Categories instead of the STS Congenital Heart Surgery Mortality Categories.)

*A *cardiac operation* is defined as an operation of operation type "CPB" or "No CPB Cardiovascular."

†This measure is applicable when one or more septal occluder devices are implanted in the course of a surgical operation for which the primary procedure of an index cardiac operation is VSD repair. A VSD device that is placed as a purely transcatheter technique, and not as a component of a cardiac operation, is classified as an *interventional cardiology procedure* and is not tracked as part of this measure.

ASD, Atrial septal defect; ASD, atrial switch operation; AV, atrioventricular; AVC, atrioventricular canal; AVSD, atrioventricular septal defect; CAVSD, complete atrioventricular septal defect; CHSDB, Congenital Heart Surgery Databases; CPB, cardiopulmonary bypass; CPS, mechanical CardioPulmonary Support; EACTS, European Association for Cardio-Thoracic Surgery; ECMO, extracorporeal membrane oxygenation; IAA, interrupted aortic arch; IABP, intra-aortic balloon pump; IAS, intact ventricular septum; LV, left ventricle; MAPCA, major aortopulmonary collateral; PA, pulmonary artery; PA-VSD, pulmonary atresia with ventricular septal defect; PA-VSD, partial ventricular septal defect; RA, right atrium; STS, Society of Thoracic Surgeons; TCPC, Total CavoPulmonary Connection; TGA, transposition of the great arteries; TEE, transesophageal echocardiography; TOF, tetralogy of Fallot; VAD, ventricular assist device; VSD, ventricular septal defect.

TABLE 133-4 Consensus Definitions of the Morbidities

Measure	Organ System	Complication	Definitions
12	Renal	Acute renal failure requiring dialysis at the time of hospital discharge	Acute renal failure* with a new postoperative or postprocedural requirement for dialysis, including peritoneal dialysis or hemodialysis. Code this complication if the patient requires dialysis at the time of hospital discharge or death in the hospital. (This complication should be chosen only if the dialysis was associated with acute renal failure.)
12	Renal	Acute renal failure requiring temporary dialysis with the need for dialysis not present at hospital discharge	Acute renal failure with a new postoperative or postprocedural requirement for temporary dialysis, including peritoneal dialysis and/or hemodialysis. Code this complication if the patient does not require dialysis at the time of hospital discharge or death in the hospital. (This complication should be chosen only if the dialysis was associated with acute renal failure.)
12	Renal	Acute renal failure requiring temporary hemofiltration with the need for dialysis not present at hospital discharge	Acute renal failure with a new postoperative or postprocedural requirement for temporary hemofiltration. Code this complication if the patient does not require dialysis at the time of hospital discharge or death in the hospital. (This complication should be chosen only if the hemofiltration was associated with acute renal failure.)
13	Neurologic	Neurologic deficit, neurologic deficit persisting at discharge	Newly recognized or newly acquired deficit of neurologic function leading to inpatient referral, therapy, or intervention not otherwise practiced for a similar unaffected inpatient, with a persisting neurologic deficit present at hospital discharge. In other words, new (onset intraoperatively, postoperatively, intraprocedurally, or postprocedurally) neurologic deficit persisting and present at discharge from hospital.
13	Neurologic	Stroke	Any confirmed neurologic deficit of abrupt onset caused by a disturbance in blood flow to the brain, when the neurologic deficit does not resolve within 24 hours.
13	Neurologic	Spinal cord injury, neurologic deficit persisting at discharge	Spinal cord injury with a persisting neurologic deficit present at hospital discharge; newly acquired or newly recognized deficit of spinal cord function indicated by physical examination findings, imaging studies, or both.
13	Neurologic	Peripheral nerve injury, neurologic deficit persisting at discharge	Peripheral nerve injury with a persisting neurologic deficit present at hospital discharge; newly acquired or newly recognized deficit of unilateral or bilateral peripheral nerve function indicated by physical examination findings, imaging studies, or both.
14	Arrhythmia necessitating pacemaker	Arrhythmia necessitating pacemaker, permanent pacemaker	Implantation and use of a permanent pacemaker for treatment of any arrhythmia including heart block (atrioventricular heart block).
15	Neurologic	Paralyzed diaphragm (possible phrenic nerve injury)	Presence of elevated hemidiaphragm on chest radiograph in conjunction with evidence of weak, immobile, or paradoxical movement assessed by ultrasound or fluoroscopy.
16	Mechanical support utilization	Postoperative or postprocedural mechanical circulatory support (IABP, VAD, ECMO, or CPS)	Use of postoperative or postprocedural mechanical support, of any type (IABP, VAD, ECMO, or CPS), for resuscitation or support during the postoperative or postprocedural time period. Code this complication if it occurs (1) within 30 days after surgery or intervention regardless of the date of hospital discharge, or (2) after 30 days during the same hospitalization subsequent to the operation or intervention.
17	Operative, procedural	Unplanned cardiac reoperation during the postoperative or postprocedural time period, exclusive of reoperation for bleeding	Any additional unplanned cardiac operation occurring (1) within 30 days after surgery or intervention in or out of the hospital, or (2) after 30 days during the same hospitalization subsequent to the operation or intervention. A <i>cardiac operation</i> is defined as any operation that is of the operation type of "CPB" or "No CPB Cardiovascular." The following operations will always be coded as "Planned Reoperation": (1) delayed sternal closure, (2) ECMO decannulation, (3) VAD decannulation, (4) removal of Broviac catheter. The following operations will always be coded as "Unplanned Reoperation": (1) reoperation for bleeding, (2) reoperation for infection, (3) reoperation for hemodynamic instability, (4) reoperation for initiation of ECMO or VAD, (5) reoperation for residual or recurrent lesion.
17	Operative, procedural	Unplanned interventional cardiovascular catheterization procedure during the postoperative or postprocedural period	Any unplanned interventional cardiovascular catheterization procedure occurring (1) within 30 days after surgery or intervention in or out of the hospital, or (2) after 30 days during the same hospitalization subsequent to the operation or intervention.

Continued

TABLE 133-4 Consensus Definitions of the Morbidities—cont'd

Measure	Organ System	Complication	Definitions
17	Operative, procedural	Unplanned noncardiac reoperation during the postoperative or postprocedural time period	Any additional unplanned noncardiac operation occurring (1) within 30 days after surgery or intervention in or out of the hospital, or (2) after 30 days during the same hospitalization subsequent to the operation or intervention.

**Acute renal failure* is defined as new onset oliguria with sustained urine output < 0.5 mL/kg/hr for 24 hours and/or a rise in creatinine > 1.5 times upper limits of normal for age (or twice the most recent preoperative/preprocedural values if these are available), with eventual need for dialysis (including peritoneal dialysis and/or hemodialysis) or hemofiltration. Acute renal failure that will be counted as an operative or procedural complication must occur prior to hospital discharge or after hospital discharge but within 30 days of the procedure. (An operative or procedural complication is any complication, regardless of cause, occurring (1) within 30 days after surgery or intervention in or out of the hospital, or (2) after 30 days during the same hospitalization subsequent to the operation or intervention. Operative and procedural complications include both intraoperative/intraprocedural complications and postoperative/postprocedural complications in this time interval.) The complication is to be coded even if the patient required dialysis, but the treatment was not instituted due to patient or family refusal.

CPB, Cardiopulmonary bypass; CPS, mechanical CardioPulmonary Support; ECMO, extracorporeal membrane oxygenation; IABP, intra-aortic balloon pump; VAD, ventricular assist device.

assessment and quality improvement initiatives. These initiatives will take on added importance as the public reporting of cardiac surgical performance becomes more common.^{143,176,177}

SUMMARY: BRIDGING THE GAP FROM ANALYSIS OF OUTCOMES TO IMPROVEMENT OF QUALITY

Clinical registries represent a foundational tool in the following interrelated process:

1. Measuring the outcomes of medical and surgical practices
2. Developing evidence for best medical and surgical practices,
3. Providing actionable feedback to clinicians, and
4. Improving quality of care and outcomes

Clinical registries are the best tool for measuring the outcomes of the processes of care.^{220,221} As described in this chapter, the ability to measure clinical outcomes properly requires using standardized clinical nomenclature, uniform standards for defining elements of data and collecting these data, strategies to adjust for the complexity of patients, techniques to verify the completeness and accuracy of data, and collaboration across medical and surgical subspecialties. All these elements exist in the ideal clinical registry.

Clinical registries can be used as a platform for developing evidence for best medical practices and performing comparative effectiveness research. The linkage of the STS Congenital Heart Surgery Database to the PHIS Database (funded by the National Institutes of Health [NIH]) exemplifies this approach.^{***} This linkage of clinical and administrative data facilitated comparative effectiveness research in the domains of perioperative methylprednisolone and outcome in neonates undergoing heart surgery¹⁹³ and antifibrinolytic medications in pediatric heart surgery.¹⁹⁴ Similarly, the NIH-funded ASCERT trial (American College of Cardiology

Foundation—Society of Thoracic Surgeons Collaboration on the Comparative Effectiveness of Revascularization Strategies trial) also used linked clinical and administrative data to compare surgical and transcatheter strategies of coronary revascularization.^{230,231} Although randomized trials have been considered by many to be the gold standard of comparative effectiveness research, recent efforts have examined the possibility of using a clinical registry as a platform for randomized trials,^{232,233} potentially accomplishing the dual objectives of decreasing the cost of the trial and increasing the generalizability of the patients enrolled.

Clinical registries can provide actionable feedback to clinicians and therefore aid in initiatives to improve quality. Clinical registries can provide practitioners with accurate and timely feedback of their own outcomes and can benchmark these outcomes to regional, national, or even international aggregate data.^{182,198,234,235,236}

The ultimate goal of clinical registries is to improve quality of care and outcomes. Clinical registries have been used to create standardized measures of quality that have been endorsed by multiple professional medical societies and the National Quality Forum.^{186,237} Compliance with these measures and the public reporting of these measures should lead to improvements in the overall quality of care delivered to our patients.^{143,176,177}

STANDARDIZATION OF METHODOLOGY

VALIDATION OF TECHNICAL PERFORMANCE SCORE

FUTURE DIRECTION

APPENDIX 134-1: BOSTON CHILDREN'S HOSPITAL TECHNICAL PERFORMANCE SCORE

BACKGROUND

According to the Centers for Disease Control and Prevention (CDC),¹ congenital heart disease (CHD) is the most common type of birth defect, affecting 1% of the population (40,000 births/year). CHD is the leading cause of illness and death associated with birth defects. Fifteen percent of all patients with CHD have associated genetic conditions, and 20% to 30% have physical, developmental, or cognitive problems.²⁻⁵ In 2004, the health care cost for hospitalization of individuals with CHD was approximately \$1.4 billion.¹ It is now feasible to offer surgical correction or palliation to most of these patients. In 2011, 33,733 congenital cardiac procedures were reported to the Society of Thoracic Surgeons (STS).⁶ Between 1999 and 2006, CHD was listed as the primary cause of death in 27,960 people. Among these, 48% were infants, often following complex interventions and prolonged ICU stay. Despite recent advances in surgical management, CHD has a significant societal impact in terms of morbidity, mortality, and health care resource utilization. Thus, this patient population presents an enormous challenge to the health care environment where optimal care can greatly influence not only short-term but also long-term physical, intellectual, and psychosocial outcomes.

Outcomes in congenital cardiac surgery are multifactorial and may be affected by (1) preoperative status, such as patient factors (e.g., birth weight, gestational age, complexity of CHD), hemodynamic stability, adequacy of diagnostic evaluation, and appropriateness of the surgical plan; (2) intraoperative factors, such as conduct of anesthesia and cardiopulmonary bypass, surgical technique, and early post-bypass hemodynamic management; and (3) postoperative course, such as serious adverse events

and complications. Among these many factors, technical adequacy of repair is likely a significant determinant of successful outcome. Indeed, the degree to which a congenital heart operation achieves its intended result may be the single most important factor determining long-term medical outcomes and costs.

Until recently, hospital mortality, often in the form of cumulative sum (CUSUM) analysis, had been used as a surrogate measure of technical performance in congenital heart surgery.⁷⁻⁹ Raw mortality data, however, do not correct for case complexity or other associated factors that can affect outcomes. One alternative, the hospital standardized mortality ratio (HSMR), is intended as an overall measure of in-hospital deaths, a proportion of which are preventable. High ratios may thus suggest potential problems with quality of care.¹⁰ The HSMR is a complex but inexpensive and relatively easy method to calculate, from national or other benchmark data, the patients' predicted risk of death. However, there are a number of methodological challenges in HSMR's construction and interpretation, largely because they are based on administrative databases.¹¹ Although risk-adjusted in-hospital death rates may be a reasonable measure of institutional performance, this measure is inadequate to assess the performance of individual physicians because many additional factors outside the control of an individual surgeon (e.g., the contribution and impact of other team members) must also be considered. This is especially problematic for high-risk operations, which require a complex multidisciplinary microsystem of dedicated teams composed of many individuals and specialties.

The technical performance score (TPS), developed to address the lack of systematic methods for evaluating operative technical adequacy across diagnoses and centers,

is a novel tool for assessing technical competency based on widely available clinical and echocardiographic characteristics.

DEVELOPMENT OF THE TECHNICAL PERFORMANCE SCORE

TPS was developed at Boston Children's Hospital to assess the adequacy of anatomic repair. The technical steps toward an adequate anatomic repair of a lesion are mostly under the control of the surgeon. Intraoperative technical excellence is one of the key factors in determining outcomes, especially in high-acuity operations.¹²⁻¹⁴ A deficit in tools available to measure technical adequacy of a surgical procedure was key to the development of the TPS. This tool was designed to be used for peer and self-assessment and was initially piloted in selected surgical procedures, including repairs of ventricular septal defect, tetralogy of Fallot, complete common atrioventricular canal, arterial switch, and, later, the stage I Norwood procedure.^{15,16} The use was then expanded to include more than 90% of congenital cardiac surgery operations.¹⁷

The score was created by dividing the surgical procedure into individual subcomponents or subprocedures, based on specific anatomic regions intervened on surgically. TPS is then assessed based on echocardiographic criteria that are designed to capture the individual components of specific operations, as well as unplanned surgical or catheter-based re-interventions prior to discharge in the anatomic areas relevant to the surgical procedure. The components of the score were defined and piloted by a modified consensus process of cardiologists and cardiac surgeons at our center. Based on these prespecified components (subprocedures) that were particular to each operation, each discharge echocardiogram could be classified into one of three categories (class 1 = optimal, class 2 = adequate, or class 3 = inadequate). If all subprocedures have a class 1 optimal score, the overall score for the entire procedure will be class 1 (optimal). If any individual subprocedure is scored as class 1 or 2, the overall TPS for the procedure will be class 2 (adequate). If any subprocedure is scored as class 3 (inadequate), or if the patient undergoes at least one surgical or catheter-based re-intervention in the anatomic area of interest prior to discharge, the TPS will be class 3. Certain specific procedures that result in an unexpected implantation of a permanent pacemaker will also result in the procedure being scored as inadequate (class 3).

PILOTING THE TECHNICAL PERFORMANCE SCORE

Initial validation was performed in four procedural groups—ventricular septal defect, tetralogy of Fallot, complete common atrioventricular canal, and arterial switch operation—using data from 2004.¹⁵ Despite significant diversity and complexity among procedures, technical adequacy of repair could be successfully determined in this group of congenital cardiac procedures using the TPS tool.

TABLE 134-1 Association between Technical Performance Score and Outcomes in the Norwood Population

	Optimal	Adequate	Inadequate	P Value
Hospital LOS median (range)	18 (2-96)	19 (4-141)	33 (1-125)	0.02
Hospital mortality	4 (5%)	2 (11%)	3 (27%)	0.02
ECMO	6 (8%)	2 (11%)	8 (53%)	<0.001

ECMO, Extracorporeal membrane oxygenation; LOS, length of stay.

The TPS tool was then validated for the stage I procedure by a retrospective analysis of 110 patients from January 2004 to December 2006. There were 77 (70%) in the optimal group, 18 (16%) in the adequate group, and 15 (14%) in the inadequate group. Inadequate technical performance was significantly associated with greater early mortality, occurrence of adverse events (such as need for extracorporeal membrane oxygenation), and length of stay (Table 134-1).¹⁶

A subgroup analysis of TPS in the Norwood population showed that optimal technical performance attenuated the effects of preoperative physiologic status and case complexity with reduced hospital mortality.¹²

STANDARDIZATION OF METHODOLOGY

As part of standardization of the tool for use among multiple institutions, we developed standardized echo protocols for echo acquisition and developed anatomic modules that could be used to standardize the images obtained by the echocardiographer performing the discharge echocardiogram. These anatomic modules (Appendix 134-1) also enable the clinician finalizing the TPS to be able to accurately score all components adequately.

VALIDATION OF TECHNICAL PERFORMANCE SCORE

In subsequent studies we were able to show that TPS was useful in predicting both short- and mid-term outcomes.^{13,18-21} Specifically, to define the relationship between TPS and major postoperative adverse events, we performed a prospective study¹³ that included intraoperative observations of operations in risk adjustment for congenital heart surgery (RACHS-1)^{22,23} categories 2 through 6 in 166 infants younger than 6 months. For the entire cohort, optimal TPS resulted in lower postoperative adverse events, lower postoperative pediatric risk of mortality (PRISM)²⁴ score, lower length of intensive care unit (ICU) stay and hospital stay, and shorter ventilation time ($P < 0.001$). Optimal TPS also resulted in low postoperative adverse events independent of RACHS-1 category, or preoperative PRISM (Fig. 134-1). In multivariable logistic regression, the strongest independent predictors of postoperative major adverse events were TPS, RACHS-1 category, and preoperative PRISM. In a

prospective follow-up study of our cohort of neonates and infants from index surgery for a minimum of 1 year, 7 of the 166 patients had early mortality.¹⁸ Among the remaining 159 patients, late death occurred in 13, and late unplanned interventions (in the anatomic area operated on at index surgery) were performed in 55. Using univariate analysis, inadequate TPS was associated with postdischarge mortality ($P < 0.0001$) and re-intervention ($P = 0.034$). However, on multivariable modeling, inadequate TPS was an independent predictor of only postdischarge mortality ($P = 0.017$) (Fig. 134-2). To expand the number of patients available for analysis and thereby to improve power, we performed a retrospective study of 725 patients who were followed for a minimum of 4 years²¹; TPS

was an independent predictor in multivariable analysis of both late postdischarge mortality and unplanned re-interventions (Fig. 134-3).

We also studied the association of TPS with neurodevelopmental outcomes using the Bayley Scale of Infant Development (BSID) III scores in a group of 140 children who underwent their initial cardiac operation in the first year of life.¹⁹ Inadequate TPS was an independent predictor of poor neurodevelopmental outcomes after adjusting for other significant patient-related factors (Table 134-2).

To enhance the simplicity and reproducibility of TPS assessment, we subsequently modified the TPS to exclude intraoperative revisions (the initial five modules included such revisions as a criterion by which TPS automatically fell to class 2 [adequate]). We created 30 procedural modules and then validated these modules by prospectively assigning TPS to all discharged patients undergoing operations for CHD at our center. All patients who were discharged between January 1, 2011, and April 30, 2013, were included in this study.²⁰ TPS was optimal in 956 (50%), adequate in 584 (30%), inadequate in 226 (12%), and indeterminate in 160 patients (8%). There were 51 (2.6%) early deaths and 111 (5.7%) major adverse events (Fig. 134-4). In univariate analyses, mortality and occurrence of adverse events were significantly associated with age, RACHS-1 categories, and TPS. In multivariable regression analyses, inadequate TPS was a strong independent predictor of mortality ($P < 0.001$; OR [odds ratio], 16.9; 95% confidence interval [CI], 6.7-42.9), adverse events ($P < 0.001$; OR, 6.9; 95% CI, 4.1-11.6), and ICU length of stay ($P < 0.001$; coefficient, 2.3; 95% CI, 2.0-2.6).

We subsequently analyzed hospital cost data in this group of patients and found that class 3 (inadequate) TPS was associated with a significantly higher hospital cost after adjusting for other significant variables such as RACHS-1 risk category, age, prematurity, genetic syndromes, presence of extracardiac nonchromosomal anomalies, weekend admissions, and the need for multiple procedures at index surgery (Table 134-3; Fig. 134-5).^{24a} TPS was an independent predictor of increased total hospital cost with the percentage of variance explained (R^2) increasing from 42% to 53% when TPS was added to the

FIGURE 134-1 ■ Major postoperative adverse events as predicted by technical performance score and risk adjustment for congenital heart surgery (RACHS-1) risk categories in a prospective cohort of 166 infants younger than 6 months of age.

FIGURE 134-2 ■ Association between technical performance score and postdischarge mortality in a prospective cohort of 166 infants younger than 6 months of age. RACHS, Risk adjustment for congenital heart surgery.

TABLE 134-2 Multivariable Analysis of Bayley Scale of Infant Development (BSID) Cognitive Composite Score Adjusting for Preoperative Factors (Total R² = 14.6%)

	Regression Coefficient (SE)	P Value	Regression Coefficient (SE)	P Value	Partial R ²
Chromosomal anomalies	-15.1 (5.3)	0.005	-14.4 (5.2)	0.007	5.4%
Nonchromosomal anomalies	-10.4 (4.2)	0.02	-10.2 (4.2)	0.02	4.2%
RACHS-1 category 6	-11.4 (5.0)	0.03	-7.7 (5.3)	0.15	1.5%
TPS (vs. optimal)					
Adequate	—		-2.4 (3.1)	0.45	3.9%
Inadequate	—		-12.5 (5.1)	0.02	

The model on the left includes all presurgical and surgical risk factors significant at the 0.10 level. The model on the right adds in TPS. Inadequate TPS was significantly associated with a lower score after adjusting for chromosomal and nonchromosomal anomalies and RACHS-1 category.

RACHS-1, Risk adjustment for congenital heart surgery; TPS, technical performance score.

FIGURE 134-3 ■ Association between technical performance score and postdischarge mortality and postdischarge unplanned re-intervention in a cohort of 725 patients followed for 4 years.

FIGURE 134-4 ■ Mortality and adverse events based on technical performance score in a prospective cohort of 1926 patients. NA, TPS could not be assigned; TPS, technical performance score.

model, indicating that TPS explained a large additional fraction of variability in total hospital cost.

To explore the predictive validity of TPS within the multicenter environment of the Pediatric Heart Network, we recently performed a secondary analysis using the

database of the Single Ventricle Reconstruction (SVR) trial. Specifically, in this 15-center study, we demonstrated that inadequate TPS was an independent predictor of longer time to extubation, higher early mortality, longer Norwood hospital length of stay (Fig. 134-6), greater

proportion of pre-stage II re-interventions and lower Psychomotor Development Index scores at 14 months after adjusting for important preoperative factors.²⁵

FUTURE DIRECTION

Mortality and adverse events are no longer considered to be major outcome measures of quality of care. With current advances in surgical and other related technologies, attention is being turned to more subtle measures such as neurodevelopmental outcomes, resource utilization in the form of length of stay, readmissions, and unplanned postdischarge re-intervention. Although the role of human factors in outcomes after surgery has been well described,²⁶⁻²⁸ technical adequacy of the repair may still be the single most important factor in determining these more subtle outcomes; this has been demonstrated in other surgical fields.²⁹⁻³¹ Models of surgical skills assessment, including video recordings of skill tests and other methods, have been developed as part of surgical training programs.³²⁻³⁵ However, the use of a routine test (i.e., a test that is clinically indicated) as a tool for assessment of technical adequacy has not been described.

Our studies have shown that technical adequacy of the repair, as measured by TPS, has emerged as an important predictor of outcomes in congenital surgery. We describe a “technical imperative,” defined as an absolute rule whereby it is imperative to leave the operating room with a good or, better yet, an optimal technical result, even if this requires surgical revision and going back on bypass.^{12-14,16} Thus, a focus on the intraoperative assessment of the adequacy of the anatomic repair, primarily by echocardiography but also by pressure measurements and even intraoperative angiography, is paramount. Increasing intraoperative vigilance so as to detect and immediately repair significant residual lesions remains of prime importance. Our studies also indicate that residual defects repaired in a timely fashion, which usually means

immediately in the operating room or within 24 hours of surgery, result in no significant impact on patient outcome, even in highly complex cases.

The development and implementation of a system for measuring technical performance in congenital cardiac surgery operations can be used not only as an outcomes measurement tool but also as a tool for surgeons’ self and peer assessments. It can help determine how much of the interinstitutional variation can be attributed to adequacy of surgical repair versus other contributory factors, such as patient- and institution-related factors. The use of the TPS in conjunction with a risk adjustment method, such as RACHS-1, Aristotle, or STS-EACTS,^{22,23,36-38} allows for quality improvement for specific risk populations and enables a structured approach to management based on procedural complexity. TPS need not be limited to congenital cardiac procedures but may be applied to adult cardiac operations and, in fact, could potentially be expanded across all surgical specialties. This system may also be applicable to noncardiac procedures, such as interventional cardiac catheterization, electrophysiologic ablations, and radiologic interventions.

Prospective multicenter validation of this tool will allow for further refinement of the score, particularly for procedures such as valve repairs and prosthetic valve replacement. Accrual of data on sufficiently large numbers in each procedural group will allow us to determine the relative importance of the various components of each procedure and will lead to the development of a weighted scale for the components of each procedure. This will then enable us to determine which patient with a TPS of class 2 or class 3 would warrant closer follow-up and perhaps earlier intervention to optimize outcomes, thus improving quality of life while minimizing resource utilization and indirectly having a positive impact on health care costs. Development of TPS for intraoperative post-bypass transesophageal echocardiograms and epicardial echocardiograms would allow for timely correction of residual defects and lead to significant improvements in physical, psychosocial, and fiscal costs.

APPENDIX 134-1: BOSTON CHILDREN'S HOSPITAL TECHNICAL PERFORMANCE SCORE

Subprocedures	1	2	3	Other Modules
Aortic Arch, Descending Aorta				
Descending aorta	No or trivial gradient Peak gradient < 20 mm Hg	Mild gradient Peak gradient 20-40 mm Hg	Moderate to severe gradient Peak gradient > 40 mm Hg	
Aortic arch	No or trivial gradient Peak gradient < 20 mm Hg No apparent narrowing by imaging or color Doppler jet width	Mild gradient Peak gradient 20-40 mm Hg or < 30% narrowing by imaging or color Doppler jet width	Moderate to severe gradient Peak gradient > 40 mm Hg or > 30% narrowing by imaging or color Doppler jet width	
Aortic Valve/Truncal Valve (Repair)				
Aortic valve repair	No or trivial stenosis	Mild stenosis	Moderate to severe stenosis	LVOT
Truncal valve repair	Peak gradient < 20 mm Hg No or trivial regurgitation VC < 1 mm if < 10 kg VC < 2 mm if > 10 kg	Peak gradient 20-40 mm Hg Mild regurgitation VC 1-2 mm if < 10 kg VC 2-4 mm if > 10 kg	Peak gradient > 40 mm Hg Moderate to severe regurgitation VC > 2 mm if < 10 kg VC > 4 mm if > 10 kg	Supra-aortic anastomosis/ repair
Aortic Valve/Truncal Valve Replacement				
Prosthetic valve implantation	Trivial or no stenosis Peak velocity < 2.5 m/sec Trivial to no regurgitation	Mild stenosis Peak velocity < 3.5 m/sec Minor paravalvular leak (VC < 2 mm)	Moderate or severe stenosis Peak velocity > 3.5 m/sec Significant paravalvular leak (VC > 2 mm)	LVOT Supra-aortic anastomosis
Autograft implantation	No aortic valvar regurgitation or stenosis VC < 2 mm	Trivial to mild regurgitation or stenosis VC 2-4 mm Peak gradient < 30 mm	Moderate or severe stenosis Peak gradient > 30 mm Moderate or severe regurgitation VC > 4 mm	LVOT Supra-aortic anastomosis
Atrial Septum/Atrial Septectomy				
Atrial septectomy	No or trivial gradient Mean gradient < 2 mm Hg (Restrictive atrial septum left on purpose; higher gradient acceptable)	Mild residual obstruction Mean gradient 2-4 mm Hg (unless intended)	Moderate to severe residual obstruction Mean gradient > 4 mm Hg (unless intended)	
ASD Repair, Patch/Primary, Common Atrium/Sinus Venosus				
ASD repair	No or trivial residual shunt <2 mm if > 10 kg <1 mm if < 10 kg	Small residual shunt 2-3 mm if > 10 kg 1-2 mm if < 10 kg	Residual shunt >3 mm if > 10 kg >2 mm if > 10 kg	
SVC (for superior sinus venosus defect)	No SVC obstruction Mean gradient < 2 mm Hg	Trivial to mild SVC obstruction Mean gradient 2-4 mm Hg	Mild or greater SVC obstruction Mean gradient > 4 mm Hg	
IVC (for inferior sinus venosus defect)	No IVC obstruction Mean gradient < 2 mm Hg	Trivial to mild IVC obstruction Mean gradient 2-4 mm Hg	Mild or greater IVC obstruction Mean gradient > 4 mm Hg	

Subprocedures	1	2	3	Other Modules
AVV Plasty				
Left AV valve plasty (subaortic AV valve)	No or trivial stenosis Mean gradient < 3 mm Hg No or trivial regurgitation VC < 1 mm if < 10 kg VC < 2 mm if > 10 kg	Mild stenosis Mean gradient 3-6 mm Hg Mild regurgitation VC 1-2 mm if < 10 kg VC 2-4 mm if > 10 kg	Moderate or severe stenosis Mean gradient > 6 mm Hg Moderate or severe regurgitation VC > 2 mm if < 10 kg VC > 4 mm if > 10 kg	
Right AV valve plasty (subpulmonary AV valve)	No or trivial stenosis Mean gradient < 3 mm Hg No or trivial regurgitation VC < 3 mm if < 10 kg VC < 4 mm if > 10 kg	Mild stenosis Mean gradient 3-6 mm Hg) Mild regurgitation VC 3-5 mm if < 10 kg VC 4-6 mm if > 10 kg	Moderate or severe stenosis Mean gradient > 6 mm Hg Moderate or severe regurgitation VC > 5 mm if < 10 kg VC > 6 mm if > 10 kg	
Tricuspid valve annulus plication (cone)	No anatomic disruption of plication No coronary injury	No anatomic disruption of plication No coronary injury	Dehiscence of plication Coronary artery injury	
RV/RA plication/ excision (cone)	No anatomic disruption of plication No coronary injury	No anatomic disruption of plication No coronary injury	Dehiscence of plication Coronary artery injury	
AVV Replacement				
Mitral valve implantation	Trivial or no stenosis Mean velocity < 1.5 m/sec No paravalvar leak (follow manufacturer's guidelines for stenosis for prosthetic valve)	Mild stenosis Mean velocity 1.5-2.5 m/ sec Minor paravalvular leak (VC < 2 mm)	Moderate or severe stenosis Mean velocity > 2.5 m/sec Significant paravalvular leak (VC > 2 mm)	Coronary
Tricuspid valve implantation	Trivial or no stenosis Mean velocity < 1.5 m/sec No paravalvar leak (follow manufacturer's guidelines for stenosis if prosthetic valve)	Mild stenosis Mean velocity 1.5-2.5 m/ sec Minor paravalvular leak (VC < 2 mm)	Moderate or severe stenosis Mean velocity > 2.5 m/sec Significant paravalvular leak (VC > 2 mm)	Coronary
Branch Pulmonary Artery Reconstruction				
Branch pulmonary artery reconstruction	No residual stenosis Peak gradient < 20 mm Hg No discrete narrowing by imaging or color Doppler jet width	Mild residual stenosis Peak gradient 20-40 mm Hg or < 30% narrowing by imaging or color Doppler jet width	Moderate to severe residual stenosis Peak gradient > 40 mm Hg or > 30% narrowing by imaging or color Doppler jet width	
BT/Sano/Other Systemic to Pulmonary Artery Shunts, Including Unifocalization				
BT/Sano/other systemic to pulmonary artery shunts	Patent	Patent	Partial or complete occlusion, distortion of branch pulmonary arteries	
Cavopulmonary Anastomosis				
SVC-PA anastomosis	No obstruction	Mild distortion or obstruction	Moderate to severe obstruction	
Main pulmonary artery patch plasty	No pulmonary artery distortion Mean gradient < 2 mm	Mean gradient 2-4 mm Hg	Mean gradient > 4 mm Hg	
IVC inflow	No or trivial obstruction Mean gradient < 2 mm Hg	Mild obstruction Mean gradient 2-4 mm Hg	Moderate to severe obstruction Mean gradient > 4 mm Hg	
Tunnel/conduit- pulmonary artery anastomosis	No or trivial obstruction Mean gradient < 2 mm Hg	Mild distortion or obstruction Mean gradient 2-4 mm Hg	Moderate to severe obstruction Mean gradient > 4 mm Hg	
Fenestration (if present)	Patent	Patent	Fenestration not patent	
Coronary Reimplantation/Unroofing				
Coronaries reimplantation/ unroofing/baffle	No obstruction to coronary flow	No obstruction to coronary flow	Coronary flow compromise, ischemia/ infarction, with echo and/or ECG findings	Aortic valve Supra-aortic anastomosis

Continued

Subprocedures	1	2	3	Other Modules
LVOT/Sub-Aortic Stenosis Resection				
LVOT	Trivial LVOT obstruction (MIG < 20 mm Hg)	Mild LVOT obstruction (MIG 20-40 mm Hg)	Moderate or severe LVOT obstruction (MIG > 40 mm Hg)	Aortic valve Supra-aortic anastomosis
PDA Ligation/Division				
PDA closure	No residual PDA	Residual PDA ≤ 1 mm	Re-intervention or Residual PDA > 1 mm	Arch and descending aorta Branch pulmonary arteries
Pulmonary Valve Intervention				
Pulmonary valve reconstruction	No residual obstruction	Mild residual obstruction	Moderate to severe residual obstruction	Suprapulmonary anastomosis
Valve sparing	RVOT peak gradient < 20 mm Hg No or mild pulmonary valve regurgitation VC < 3 mm if < 10 kg VC < 5 mm if > 10 kg	RVOT peak gradient 20-40 mm Hg Mild PR VC 3-5 mm if < 10 kg VC 5-8 mm if > 10 kg	RVOT peak gradient > 40 mm Hg Moderate to severe PR VC > 5 mm if < 10 kg VC > 8 mm if > 10 kg	Main pulmonary artery Branch pulmonary arteries
Transannular patch	No residual obstruction RVOT peak gradient < 20 mm Hg PR—no consequence	Mild residual obstruction RVOT peak gradient 20-40 mm Hg PR—no consequence	Moderate to severe residual obstruction RVOT peak gradient > 40 mm Hg PR—no consequence	Suprapulmonary anastomosis Main pulmonary artery Branch pulmonary arteries
Pulmonary Valve Replacement				
Pulmonary valve replacement	Trivial or no stenosis Peak velocity < 2.5 m/sec No paravalvular leak (follow manufacturer's guidelines for stenosis if prosthetic valve)	Mild stenosis Peak velocity 2.5-3.5 m/sec Minor paravalvular leak (VC < 2 mm)	Moderate or severe stenosis Peak velocity > 3.5 m/sec Significant paravalvular leak (VC > 2 mm)	Suprapulmonary anastomosis Main pulmonary artery Branch pulmonary arteries Subpulmonary outflow
Pulmonary Veins				
Pulmonary vein confluence or baffle	No or trivial obstruction Mean gradient < 2 mm Hg	Mild obstruction Mean gradient 2-4 mm Hg	Moderate or severe obstruction Mean gradient > 4 mm Hg	
Scimitar vein baffle to left atrium	No or trivial obstruction Mean gradient < 2 mm Hg	Mild obstruction Mean gradient 2-4 mm Hg	Moderate or severe obstruction Mean gradient > 4 mm Hg	
Unroofing of coronary sinus	No obstruction Mean gradient < 2 mm Hg	Mild obstruction Mean gradient 2-4 mm Hg	Moderate or severe obstruction Mean gradient > 4 mm Hg	
RVOT Reconstruction/Sub-Pulmonary Stenosis Resection				
Relief of RVOT obstruction	No or trivial residual obstruction Peak gradient < 20 mm Hg	Mild residual obstruction Peak gradient 20-40 mm Hg	Moderate or severe residual obstruction Peak gradient > 40 mm Hg	Pulmonary valve Suprapulmonary Branch pulmonary arteries
RV-PA Conduit				
RV-PA conduit	Trivial to no valvar stenosis Peak gradient < 20 mm Hg Trivial to no valvar regurgitation VC < 3 mm	Mild stenosis Peak gradient 20-40 mm Hg Mild regurgitation VC 3-5 mm	Moderate or severe stenosis Peak gradient > 40 mm Hg Moderate or severe regurgitation VC > 5 mm	Subpulmonary Suprapulmonary Branch pulmonary arteries

Subprocedures	1	2	3	Other Modules
Supra-aortic Anastomosis/Repair				
Ascending aortic reconstruction	No residual gradient or narrowing	Mild narrowing or mild residual gradient	Moderate or severe residual stenosis	Aortic valve
Supra-aortic anastomosis	Peak gradient < 10 mm Hg	Peak gradient 10-20 mm Hg	Peak gradient > 20 mm Hg	Aortic arch
Suprapulmonary Anastomosis/Repair				
Main pulmonary artery reconstruction	No residual gradient or narrowing	Mild narrowing or mild residual	Moderate or severe residual stenosis	Pulmonary valve
Suprapulmonary anastomosis	Peak gradient < 10 mm Hg	Peak gradient 10-20 mm Hg	Peak gradient > 20 mm Hg	Branch pulmonary arteries
Systemic Venous Baffle				
Systemic venous baffle	No or trivial obstruction Mean gradient < 2 mm Hg	Mild obstruction Mean gradient 2-4 mm Hg	Moderate to severe obstruction Mean gradient > 4 mm Hg	
Transplant				
Left atrium anastomosis	No or trivial obstruction Mean gradient < 2 mm Hg	Mild obstruction Mean gradient 2-4 mm Hg	Moderate or severe obstruction Mean gradient > 4 mm Hg	
Aortic anastomosis	No obstruction Peak gradient < 10 mm	Mild obstruction Peak gradient 10-20 mm Hg	Moderate or severe obstruction Peak gradient > 20 mm Hg	
Pulmonary artery anastomosis	No obstruction Peak gradient < 10 mm Hg	Mild obstruction Peak gradient 10-20 mm Hg	Moderate or severe obstruction Peak gradient > 20 mm Hg	
SVC/IVC anastomosis	No or trivial obstruction Mean gradient < 2 mm Hg	Mild obstruction Mean gradient 2-4 mm Hg	Moderate or severe obstruction Mean gradient > 4 mm Hg	
PFO closure	No or trivial residual shunt <2 mm if > 10 kg <1 mm if < 10 kg	Small residual shunt 2-3 mm if > 10 kg 1-2 mm if < 10 kg	Residual shunt >3 mm if > 10 kg >2 mm if > 10 kg	
Ventricular Assist Devices				
Left ventricular/left atrial cannula	No obstruction to flow	Mild obstruction	Moderate or severe obstruction	
Ascending aortic cannula	No obstruction Peak gradient < 10 mm Hg	Mild obstruction Peak gradient 10-20 mm Hg	Moderate or severe obstruction Peak gradient > 20 mm Hg	
Pulmonary artery anastomosis	No obstruction Peak gradient < 10 mm Hg	Mild obstruction Peak gradient 10-20 mm Hg	Moderate or severe obstruction Peak gradient > 20 mm Hg	
Right atrial cannula	No obstruction	Mild obstruction	Moderate or severe obstruction	
VSD Repair				
VSD repair	No or trivial residual shunt <2 mm if > 10 kg <1 mm if < 10 kg	Residual defect 2-3 mm if > 10 kg 1-2 mm if < 10 kg	Residual defect >3 mm if > 10 kg >2 mm if < 10 kg	Aortic valve Tricuspid valve

If PFO was left open, fenestrated ASD closure was performed, or fenestrated VSD closure was performed, then ASD and VSD were not scored. Additional muscular VSDs not intervened on at time of surgery also were not scored.

ASD, Atrial septal defect; AV, atrioventricular; AVV, atrioventricular valve; BT, Blalock-Taussig; ECG, electrocardiogram; IVC, inferior vena cava; LVOT, left ventricular outflow tract; MIG, maximum instantaneous gradient; PFO, patent foramen ovale; PR, pulmonary regurgitation; RVOT, right ventricular outflow tract; RV-PA, right ventricle to pulmonary artery; SVC, superior vena cava; SVC-PA, superior vena cava to pulmonary artery; VC, vena contracta; VSD, ventricular septal defect.

 myocardial oxygen consumption (MVO₂), 840
 ventricular function efficiency, 840
- non-Starling regulation mechanisms, 839
- overviews of, 831
- pump function, 839
 force frequency relationship, 839
 Frank-Starling relationship, 839, 840f
- regional strain, 841-842, 842f
 definition of, 841
 echocardiography and, 842
 implanted markers, 841
 magnetic resonance imaging (MRI) and, 842
 second-order tensors, 841
 spatial modulation of magnetization (SPAMM) and, 842
- regional stress, 842-846, 843f
 Acorn CorCap Cardiac Support Device (Acorn CSD), 844, 845f
 definition of, 842-843, 843f
 finite element method, 843-844

- Ventricular mechanics (*Continued*)
 inverse calculations, 844
 multiscale modeling, 845-846
 myocardial material parameters, 844
 stress calculations, 844
 virtual surgery, 844-845, 846f
 systolic function, 836-839
 cardiac index (CI), 836
 cardiac output (CO), 836
 ejection fraction (EF), 837-838
 end-systolic elastance, 836-839
 end-systolic pressure-volume relationship (ESPVR), 833-834, 838f
 Fick principle, 836-837
 heart rate (HR), 836
 myocardial ischemia, 839
 stroke volume (SV), 836
 Swan-Ganz catheters, 836-837
 systolic dysfunction, 839
 ventricular interaction, 846-847
 analyses of, 846, 847f
 pericardium and, 846-847. *See also* Pericardium.
 ventricular tissue structures, 831-832, 832f-833f
 extracellular matrix (ECM), 832
 myocardium, laminar organization of, 832
 myocyte orientation, 832
 ventriculoarterial coupling, 840-841
 Ventricular rupture, postinfarction, 1653-1662. *See also* Ruptures.
 Ventricular septal defects (VSDs), 2097-2112
 anatomic classification of, 2098-2100, 2099f
 conal, 2099-2100
 conoventricular defects, 2098-2099
 infundibulum, 2099-2100
 inlet (atrioventricular canal type), 2100
 muscular, 2100
 outlet, 2099-2100
 supracristal, 2099-2100
 anatomy of, 2097-2100
 apical trabecular septum, 2098, 2098f
 atrioventricular (AV) canal, 2098, 2098f
 conal septum, 2098, 2098f
 conduction system, 2097-2098
 infundibular septum, 2098, 2098f
 inlet septum, 2098, 2098f
 membranous septum, 2098, 2098f
 moderator band, 2098, 2098f
 muscular septum, 2098, 2098f
 parietal band, 2098, 2098f
 septal band, 2098, 2098f
 sinus septum, 2098, 2098f
 trabecula septomarginalis, 2098, 2098f
 tricuspid valve (TV), 2097-2098
 ventricular septum, right, 2097-2098, 2098f
 commonly associated defects of, 2100
 aortic coarctation, hemodynamically significant, 2100
 atrial septal defects (ASDs), 2100
 congenital stenosis, valvar vs. subvalvar, 2100
 patent ductus arteriosus (PDA), 2100
 definition of, 2097
 diagnosis and workup for, 2101
 vs. double-outlet right ventricle (DORV), 2106-2111. *See also* Double-outlet right ventricle (DORV).
 historical reviews of, 2097
 natural history of, 2101
 pathophysiology of, 2100-2101
 pulmonary blood flow/systemic blood flow (Qp/Qs) ratio, 2100
 pulmonary vascular disease (PVD), 2100-2101
 shunts, direction vs. magnitude, 2100
 shunts, left-to-right, 2100
 Ventricular septal defects (VSDs) (*Continued*)
 postinfarction, 1653-1662
 surgical indications for, 2101
 surgical interventions for
 with associated anomalies, 2102-2105
 indications for, 2101
 outcomes, early vs. late, 2106
 postoperative care, 2105-2106
 techniques, 2101-2106, 2102f-2105f
 Ventricular suction, 835, 837f
 Ventricular tissue structures, 831-832, 832f-833f
 extracellular matrix (ECM), 832
 myocardium, laminar organization of, 832
 myocyte orientation, 832
 Ventriculoarterial coupling, 840-841
 Venules, 802
 Vertebral-anal-cardiac-tracheal-esophageal-renal-limb (VACTREL) patterns, 153, 158, 161
 Video-assisted thoracic surgery (VATS)
 for empyema, 470-471
 for lung cancers, 318-326
 complications of, 324
 contraindications for, 319-320
 cost-effectiveness, 324
 definition of, 318
 historical reviews of, 319
 indications for, 319
 locally advanced disease, 324-325
 oncologic effectiveness, 323-324
 outcomes, 323-324
 overviews of, 318, 325
 postoperative pain, 323
 pulmonary function tests (PFTs), 323
 segmentectomy, 322
 systemic inflammatory effects, 323
 thoracoscopic lobectomy, 320-321, 321f-322f
 wedge resection, 322
 for mediastinal examinations, 726
 for penetrating trauma, 119, 122-123, 124b
 for spontaneous pneumothorax (SP), 462, 463t, 464-465
 for vascular rings, 2039-2040
 Viral activation, 503-504. *See also* Mesothelioma.
 Viral infections, 255, 256f
 Virtual crossmatch (VXM), 1733
 Virtual surgery, regional stress and, 844-845, 846f
 Visceral situs, 1874-1875, 1875f
 Vitamin K
 antagonist-associated coagulopathy reversal, 863
 antagonists, 853-854
 Volume
 end-diastolic pressure-volume relationship (EDPVR), 831, 834, 834b
 end-diastolic volume (EDV), 818-819
 end-systolic (ESV), 818-819
 end-systolic pressure-volume relationship (ESPVR), 833-834, 838f
 pressure-volume
 analyses, 833-834, 834f-835f
 loop, 833
 stroke (SV), 818-819
 Von Willebrand factor (VWF), 852, 855, 862, 974
 V/Q scans. *See* Ventilation-perfusion (V/Q) scans.
